

Encyclopedia of Condensed Matter Physics

Second Edition

Volume

1

Tapash Chakraborty
Editor-in-Chief

About the pagination of this eBook

This eBook contains a multi-volume set.

To navigate this eBook by page number, you will need to use the volume number and the page number, separated by a hyphen.

For example, to go to page 5 of volume 1, type "1-5" in the Go box at the bottom of the screen and click "Go."

To go to page 5 of volume 2, type "2-5" ... and so forth.

ENCYCLOPEDIA OF CONDENSED MATTER PHYSICS

SECOND EDITION

ENCYCLOPEDIA OF CONDENSED MATTER PHYSICS

SECOND EDITION

EDITOR-IN-CHIEF

Tapash Chakraborty*

Professor, Tier-I Canada Research Chair, University of Manitoba, Winnipeg, MB, Canada

VOLUME 1

*Retired.

EDITOR-IN-CHIEF BIOGRAPHY

Tapash Chakraborty is a retired professor of physics from the University of Manitoba, Canada, where he was also the Canada Research Chair in Nanoscale Physics (2003–17). His research focus has been on many-body theories of various quantum materials, such as nuclear matter, helium liquids, and electron-hole liquids, that he studied under the tutelage of late Professor Manfred Ristig, at the University of Köln (1979–81). Just a year after the discovery of the fractional quantum Hall effect, he (working with his coworkers) demonstrated that electron–electron interactions could actually lead to quantum Hall states with nontrivial spin configurations, and that the low-lying excitations could be described as “spin-reversed quasiparticles.” This prediction motivated much experimental work from laboratories around the world, as a result of which the concept of spin-reversed quasi-particles was established.

Similarly, his work on the quantum Hall states in double layer systems has received much attention from the community. Furthermore, Dr. Chakraborty (working with Dr. P. Maksym and others) made pioneering contributions to the many-electron theory of quantum dots. Dr. Chakraborty has also contributed to the theory of electronic properties of various nanoscale systems, such as spin-orbit coupled quantum dots, quantum rings, and single- and double-layer graphene (primarily with Dr. V. Apalkov). He has authored many books and reviews: the book with Dr. Pietiläinen on the quantum Hall effect and the single-authored book on quantum dots have become standard references in their respective fields.

INTRODUCTION

Electrons in orbits contained by the quantum,
And atoms conjoined by the dipolar force,
Gravity balanced by pressure
And flap of a wing.
Here, I remember the angles and curves,
Calculus, I learned it all –
Each bird bit and moon fracture
Fixed by the symmetries,
Airborne and airless, aloft.

– Alan Lightman: *Song of Two Worlds*

Condensed matter physics (CMP) is the largest discipline in physics, involving a wide variety of interesting concepts and challenges. To quote [Leggett \(1992\)](#), CMP embraces topics “as diverse as traditional solid-state physics, neutron stars and the physics of biological matter.” He further added that, by a liberal definition “just about all of physics outside atomic, nuclear and particle physics and cosmology” fall in this vast enterprise¹. One of the primary goals of CMP is to explore the fundamental properties of matter—solids, liquids or gasses—comprising a large number of *interacting* constituent particles ([Laughlin and Pines, 2000](#)). The quantum-mechanical nature of these many-body systems makes condensed-matter highly nontrivial, sometimes counterintuitive and even astonishing. Superconductivity and the fractional quantum Hall effect (FQHE) naturally fall within that category. In fact, for the past four decades, the quantum Hall effects (QHEs) have been the epitome of elegant CMP ([von Klitzing et al., 2020](#)). Our fundamental system of units has been redefined following the discovery of the QHE when the “von Klitzing constant” $R_K = 25,812.8074593045 \, \Omega$ came into being ([von Klitzing, 2019](#); [Nawrocki, 2019](#)). Observation of the QHE in graphene² was crucial in determining the Dirac nature of charge carriers there (see for example, [Jiang et al., 2007](#)).

Another effect that outwardly resembles the QHE but is conceptually quite different is the FQHE, which is a quintessential manifestation of electron correlations governed by the Coulomb interaction ([Störmer, 1992](#); [Eisenstein and Stormer, 1990](#)). To explain this fascinating effect, [Laughlin \(1983\)](#) introduced his eponymous wave function that not only provided the foundation for understanding the effect but also triggered a new wave of ideas with impact far beyond the realm of CMP³. Who would have imagined that a large collection of interacting electrons confined on a plane in a perpendicular magnetic field would result in elementary excitations (quasiholes and quasiparticles) ([Chakraborty and Pietiläinen, 1988, 1995](#); [Halperin, 1983](#); [Clark and Maksym, 1989](#)) carrying fractional electron charge and obeying the exotic exchange statistics of anyons ([Halperin, 1984](#); [Arovas et al., 1984](#))? These quasiparticles and quasiholes of the Laughlin state still remain an enigma ([Laughlin, 1984](#); [Chakraborty, 1985](#); [Morf and Halperin, 1986](#)). Fractional statistics is a truly path-breaking concept in CMP that was introduced by [Leinaas and Myrheim \(1977\)](#), and has been recently confirmed experimentally ([Bartolomei et al., 2020](#); [Nakamura et al., 2020](#)).

Much of the history of CMP can be viewed as a series of paradigm shifts⁴. The field evolved rapidly through frequent ground-breaking discoveries that challenged existing paradigms and opened up new applications, and this evolution is expected to continue ([Leggett, 2018](#); [Cohen, 2008](#)). For example, our current understanding of

¹Interestingly, some similarities do exist between the mathematical frameworks that describe low-temperature CMP and early-universe cosmology. See [Kibble and Srivastava \(2013\)](#).

²An isolated single layer of graphite consisting of carbon atoms bonded together in a hexagonal structure. See, e.g., [Abergel et al. \(2010\)](#).

³For example, an important aspect of Laughlin's theory is its seamless concinnity of classical plasma physics and the planar electron gas that has inspired others to use a similar approach to quark-gluon plasma ([Lu, 2022](#)).

⁴A detailed exposition of the meaning and examples of “paradigm shifts” (Kuhn-type) can be found in [Leggett \(2018\)](#).

the FQHE required deep mathematical analysis and a wide range of experimental exploration, which revealed a treasure trove of unique phenomena that are yet to be fully understood or explained. Other studies of electron correlations in low spatial dimensions have ushered in many groundbreaking notions, such as Pfaffian states, Majorana fermions in condensed matter, Chern insulators, and topological quantum materials that promise a fault tolerant means to perform quantum computation. The presence of incompressible FQHE states in monolayer graphene (Apalkov and Chakraborty, 2006), bilayer graphene (Apalkov and Chakraborty, 2010, 2011), and double-layer graphene (Liu et al., 2019) has demonstrated the robustness of the effect, and provides invaluable insight into the nature of this effect.

The dynamics of an electron in a periodic potential subjected to a perpendicular magnetic field has been an intriguing problem for more than half a century (Obermair and Wannier, 1976; Osadchy and Avron, 2001)⁵. Within the nearest neighbor tight-binding description of the periodic potential the electron energy spectrum is described by the Harper equation (Harper, 1955). Numerical solution of this equation (Hofstadter, 1976) has revealed that the applied field splits the Bloch bands into subbands and gaps. As the field is varied, the splitting of band continues indefinitely, leading to bands within bands within bands. When plotted as a function of the magnetic flux per lattice cell, the energy spectrum depicts a *fractal* pattern (a self-similar pattern that repeats at every scale) and is known in the literature as Hofstadter's butterfly because of the resemblance of the pattern to butterflies⁶. Observation of the butterfly spectra in real systems is an arduous task. For example, in ordinary crystalline lattices, the required magnetic field to see the butterflies exceeds 1000 Tesla, which is far beyond the reach of present-day technology. Graphene seems to be the ideal system in the quest of those fractal butterflies (Weiss, 2013). It is interesting to note that a mathematical solution of the Harper equation, in contrast to the numerical solution mentioned above, remained a challenging problem (the so-called Ten Martini Problem) for mathematicians until it was solved (Avila and Jitomirskaya, 2006) in 2006.

Magnetism has been known to mankind since ancient times, and it remains a major topic in CMP. The road to understanding magnetism has been long and tortuous. At various times in history, magnets were claimed to have the healing power to cure a myriad of ailments that included epilepsy, arthritis, gout, and baldness. Magnets were the prime ingredients for the "elixir of life" by Paracelsus (1493–1541). Then there was the healing process of "animal magnetism" proposed by Franz Anton Mesmer (1734–1815) (mesmerism)⁷, which was famously mocked in Mozart's *Così fan tutte* (Stephoe, 1986). Our current understanding of magnetism is deeply rooted in quantum mechanics as Van Vleck explained (Van Vleck, 1978): "Quantum mechanics is the key to understand magnetism. When one enters the first room with this key there are unexpected rooms beyond, but it is always the master key that unlocks each door." For centuries, the magnetism of certain rocks and metallic iron was only used for the practical purposes of direction finding, particularly navigation with a compass. Motors, generators, and electrical distribution networks appeared only in the 19th century after the discovery of the deep connection between electricity and magnetism. Magnetic order is a collective phenomenon akin to superconductivity and superfluidity that involves a very large number of particles. The rich variety of magnetically ordered states in solids, not only ferromagnetism but also antiferromagnetism, ferrimagnetism, and a range of noncollinear structures, was confirmed only in the middle of the 20th century, with the availability of neutron beams in research reactors. A range of new magnetic materials are taking their place as active layers in thin film sensors and memory devices (Baltz et al., 2018). Besides information storage (Blundell, 2001), important technical applications include magnetic resonance imaging (MRI) and the use of magnetic nanoparticles in medicine.

Many outstanding discoveries in magnetism and magnetic materials have resulted in rapid advances in information storage technology. Over the last two decades spintronics has emerged as an important field of research both from the point of view of fundamental science and advanced technological applications (Yamaguchi et al., 2021; Pinarbasi and Kent, 2022). The giant magnetoresistance (GMR) effect, the spin Hall effect, and the spin galvanic effects are typical examples of developments in the field. Spintronics aims at understanding how the spin degree of freedom of the electrical carriers can be controlled in order to obtain devices with new functionalities and better performance. This endeavor often combines concepts from different aspects of condensed matter systems, giving the topic a fascinating interdisciplinary flavor. Spintronic phenomena are now being studied in an impressive range of different materials ranging from metals to half-metals to semiconductors, graphene and other two-dimensional systems such as transition metal dichalcogenides.

⁵For a recent review on butterflies in graphene, see for example Chakraborty and Apalkov (2015).

⁶However, as one of the authors of this Encyclopedia has (somewhat humorously) pointed out, this butterfly has Lebesgue measure zero, that is, it cannot fly!.

⁷A wonderful account of the use of magnetism in medicine since ancient times can be found in Mourino (1991).

The GMR effect and the related tunnel magnetoresistance effect (TMR) found their first commercial use in magnetic field sensors for hard-disk read-heads, before broadening their field of application to include magnetic sensors for the automobile industry, solid-state compasses, biosensors, and nonvolatile magnetic memory (Hartmann, 2000). The ability to manipulate the magnetic state of ferromagnetic structures led to initial developments in spintronics, where the spin direction was controlled by externally applied magnetic fields. However, the push for downscaling and faster timescales has prompted research advances in the past decade where the manipulation of magnetic configurations is achieved by local electric currents (the spin torque effect) (Brataas et al., 2012; Locatelli et al., 2014). In recent years, various novel concepts, such as chiral spintronics, skyrmionic spin textures, and magnetic domain walls in spintronics, have been actively pursued. The rate of progress in spintronics is truly astounding (Editorial, 2022).

In the past century, superconductivity has raised many theoretical challenges and triggered numerous technical developments. Discovered in mercury in 1911, this unique phenomenon occurs when the electrical resistance of many metals and alloys drops to zero when cooled below about 4 K, the temperature of liquid helium. More significantly, the material expels magnetic flux and becomes perfectly diamagnetic. Superconductivity has been adopted or evaluated for a wide range of technical applications (Rogalla and Kes, 2012). These include electric power generation, electric power transmission, high-speed maglev transportation, and ultra-strong magnetic field generation in high-resolution MRI and other nuclear magnetic resonance (NMR) systems. Interestingly, it took almost 50 years after the original discovery for the phenomena to be explained by the BCS theory (Tinkham, 2004) of reciprocal-space electron pairing, via the electron–phonon interaction. This electron–phonon mediated superconductivity became known as “conventional superconductivity” after the discovery of “high-temperature superconductivity” (Müller and Bednorz, 1987) at liquid nitrogen temperatures in tetragonal copper oxides in 1986. This threw open a new challenge to explain the properties of strongly correlated *anisotropic* electronic systems. Further new classes of superconductors that remain to be properly understood include the iron-based pnictides discovered in 2008 (Hosono et al., 2018). Recently, a two-dimensional superlattice made from a twisted bilayer of “magic angle” graphene was found to exhibit unconventional superconductivity (Cao et al., 2018), driven by electron–electron interactions.

The phenomenon of spontaneous symmetry breaking (SSB) is ubiquitous in physics, and plays a fundamental role in CMP, particle physics, and even in cosmology. A classic illustration of SSB being Heisenberg’s 1928 paper on ferromagnetism (Heisenberg, 1928). It is responsible for various collective modes, such as the famous Nambu-Goldstone (NG) and Higgs modes. Named by Baker and Glashow (Baker and Glashow, 1962), SSB corresponds to the case where the ground or lowest-energy state does not have the symmetry of the underlying dynamics. Instead, multiple degenerate ground states are available and the symmetry breaking is *spontaneous* because it is not clear, a priori, which one of those ground states will be chosen. In this well-trodden territory a simple analogy of this abstruse concept given by A. Salam is illuminating (CERN, 1977): “Imagine a banquet where guests sit at round tables. A bird’s eye view of the scene presents total symmetry, with serviettes alternating with people around each table. A person could equally well take a serviette from his right or from his left. The symmetry is spontaneously broken when one guest decides to pick up from his left and everyone else follows suit.” Over the years, development of the concept of SSB has taken a circuitous route (Gaudenzi, 2022): “from the land of particle physics to the physics of many bodies (solids and nuclei), from there to the province of superconductivity, and from the latter back to particle physics” SSB’s significance extends beyond the physics of the Higgs boson to the study of low-energy phenomena such as superconductivity, superfluidity, magnetism, and others. Historically, the particle physics community has been guided by this exploration in their quest to understand and discover particles like the Higgs boson. More to the point, when a continuous symmetry is spontaneously broken, a gapless mode, the NG mode, appears which governs the low-energy behavior of the system. As an example, in a solid, the acoustic phonon is the NG mode associated with translational symmetry breaking and determines the behavior of the specific heat at low temperature (the Debye T^3 law). Recently, signatures of Higgs and Goldstone modes have been proposed to exist in a perovskite oxide (Marthinsen et al., 2018), in other crystalline structures (Vallone, 2019), and also in various other quantum systems (Léonard et al., 2017). On a lighter note, it is the symmetry breaking that is claimed to have prevented the fabled donkey (Weintraub, 2012) in the parable by Jean Buridan (1300–50) from dying of starvation (Fubini, 1974).

Common to the theoretical descriptions of these phenomena across CMP and high-energy physics is Quantum field theory (QFT). QFT was originally developed to describe the fundamental processes in high-energy physics, but has now become a valuable tool to address problems across physics, in particular, in CMP (Fradkin, 2013; see also, Mustafa, 2023), statistical physics, modern quantum chemistry, and even in

pure mathematics (Folland, 2008). Advances in our understanding of strongly correlated electron systems in CMP such as high-temperature superconductivity and the FQHE have been aided by the QFT. It has facilitated the treatment of spontaneous symmetry broken states, such as superfluids. Interestingly, many of the conceptual developments in CMP have, in return, had a reciprocal impact in QFT. A spectacular example being Nambu's work in dynamical symmetry breaking (Weinberg, 1986; Nambu, 2009) in particle physics, based on the BCS theory of superconductivity.

A glass is a noncrystalline solid obtained by quenching a liquid. It has a liquid-like structure, but a transition from liquid to solid behavior occurs on cooling. It may have one of a continuum of possible ground states that exhibit frozen-in liquid-like disorder. The term “spin glass” was coined by B.R. Coles (Mydosh, 1993) in 1970 for a diluted magnetic material with frozen-in paramagnetic-like spin disorder where the magnetic moments interact with randomly varying positive or negative exchange interactions leading to a multitude of possible ground states with different, random orientations of the spins. As in a normal glass, the energy barriers between the continuum of metastable states prevent it from ever reaching equilibrium. This phase of condensed matter has been an important and productive area of research. Spin-glass models are conceptually simple, but embody sophisticated physics. These models have become a paradigm for the solution of complex optimization problems (Mézard, 2022): much like the undulating flight patterns of starlings around the skies over Rome (Parisi, 2023). After cooling from the paramagnetic phase, the spin glass remains out of equilibrium, and it slowly evolves. This aging phenomenon corresponds to the growth of a “spin-glass order” parameter, whose correlation length can be measured (Joh et al., 1999). A cooling temperature step during aging causes a partial “rejuvenation,” while the “memory” of previous aging is stored and can be retrieved (Refregier et al., 1987; Bouchaud et al., 2001). Many glassy materials present aging, and rejuvenation and memory effects can be found in other cases, but they are usually less pronounced. Numerical simulations of these phenomena are under active investigation using custom-built computers (Baity-Jesi et al., 2023; Vincent, 2023). A general understanding of glassy systems, to which spin glasses bring some special insight, is being pursued. It was realized decades ago that the physics of spin glasses has deep connections with the behavior of complex biological systems. In fact, spin-glass type states in neural network models offer interesting insights into states of high and low brain activity, as observed in mammals (Recio and Torres, 2016). These analogies are potentially useful for applications in fields such as robotics and artificial intelligence (AI) (Andriuschenko et al., 2022).

One of the most spectacular phenomena in CMP, discovered in the last century, was Bose-Einstein condensation (BEC). This macroscopic quantum phenomenon had its genesis in the work of Satyendra Nath Bose (Bose, 1924; Blanpied, 1972; Tomczyk, 2022) (whose name is forever associated with bosons), and has fascinated physicists for decades, ever since the first observation of this exotic state of matter in an ultracold gas of rubidium atoms (Georgescu, 2020). Among the advances made in this field, we highlight only a few: simulation of correlated electron states, such as the FQHE state and a bosonic analog of the Laughlin state, and the famous BEC-BCS crossover from a BEC to a BCS superfluid of weakly bound Cooper pairs, as the interparticle interaction strength is varied. Noteworthy is the recent measurement of the dynamic structure factor in an ultracold Fermi gas of lithium-6 atoms in the “unitary” limit, where a linear phonon mode for low momentum transfer can be clearly discerned (Biss et al., 2022). Perhaps such a method might one day shed light on the Laughlin quasiparticle gap and the collective modes that are still largely unresolved (Chakraborty and Pietiläinen, 1988, 1995; Halperin, 1983; Clark and Maksym, 1989).

Liquid helium, ^4He , and the less common isotope ^3He are unique quantum systems (Volovik, 2009). They remain liquid even at absolute zero temperature, a direct manifestation of Heisenberg's uncertainty principle and zero-point energy. The light mass of helium atoms and their weak interatomic attraction leads to a substantial zero-point kinetic energy and the system remains in the liquid state at ambient pressure. Solidification occurs when a pressure of about 25 MPa is applied. The different quantum statistics of the two helium isotopes (^4He is a boson while ^3He is a fermion) are responsible for the different physical characteristics of the two systems. Microscopic approaches to understand the ground state and low-energy excitations of the liquid state have occupied researchers for many decades (see for example, Ristig and Clark, 1976; Lam et al., 1977). These highly correlated quantum fluids have been established as systems where the efficacies of different many-body theories can be tested (Kallio and Smith, 1977; Lantto et al., 1977). These systems have been described as Ariadne's thread in this Encyclopedia, where the strongly interacting constituent particles are treated by a variety of ingenious theoretical and experimental approaches. Interestingly, liquid helium has been proposed to be a medium to design multiexcitation detectors to probe *dark matter* (Schutz and Zurek, 2016) in the keV mass limit. Although this looks far afield from CMP, the interface between CMP and high-energy particle physics could inspire new horizons in CMP, as discussed earlier.

CMP also has an enormous impact on our daily lives with unceasing technological innovation stemming directly from the advances in CMP research. It is also closely associated with the progress of our understanding of materials science and mechanical, chemical, and electrical engineering that deals with properties of novel materials and devices. As some authors have very aptly pointed out (Chaikin and Lubensky, 1995): The use and understanding of matter in its condensed (liquid or solid) state have gone hand in hand with the advances of civilization and technology since the first use of primitive tools. So important has the control of condensed matter been to man that prehistoric ages—the Stone Age, the Bronze Age, the Iron Age—are named after the material dominating the technology of the time. In fact, modern civilization is entirely dependent on our deep understanding and practical use of materials, old and new: Steel, glass, and concrete have shaped our modern living with comfort, health, longevity, and material wealth. All around us, from a tiny paper clip to giant skyscrapers, from jet planes to modern medicines, and the ubiquitous plastics that are integrated into nearly all aspects of human life, are testaments to our control over the myriad behavior of materials (Miodownik, 2014). Today, a large number of materials are designed by using principles of quantum mechanics (Freeman, 2002).

The Silicon chip that launched the information age is a great example of the effect of CMP on our daily lives. The scaling of transistors down to the nanometer range has enabled them to be embedded in greater numbers in the all-pervasive electronic devices that have transformed every facet of life all around the world. The transition from room-size to pocket-size computers with ever increasing computational power and memory, that occurred in only a few decades, epitomizes the unrelenting progress made in this direction. Advances in nanoscale research have opened the door to exploration of the natural world at the ultra-small scale (Chakraborty, 2022), with the potential to shape our future world.

Quantum dots (QDs), the quasi-zero-dimensional electron systems, are one of the most extensively studied nanostructures in the past three decades. They represent the ultimate reduction in dimensionality of a semiconductor device. Here the electrons are confined (either electrostatically or structurally) in all three directions and occupy spectrally sharp energy levels similar to those found in atoms (Chakraborty, 1999), hence the popular moniker *artificial atoms* (Maksym and Chakraborty, 1990). QDs and other similar nanostructures (Chakraborty, 2003) offer a rich variety of fundamental phenomena that result from manipulation of single electrons (single electronics) or single spins at the nanoscale. The study of interacting electrons in a QD requires large-scale numerical computations involving matrices of dimensions in the millions (“monster matrices”) (Chakraborty and Pietiläinen, 2005; Pietiläinen and Chakraborty, 2006). QDs are also thought to have vast potential for future technological applications. One prominent example being quantum cryptography where the QDs are used in single photon emitters (Nowak et al., 2014), and in single photon detectors (Shields et al., 2000). Quantum cryptography, in turn, forms the basis of the *quantum Internet* (Liao et al., 2018). Other applications include lasers, and spintronics in quantum computing, entertainment industry (Bourzac, 2013), and even in biology (Bruchez and Holz, 2007).

Research in recent years has increasingly revealed that quantum phenomena are also ubiquitous in the natural world (Ball, 2011). They govern how birds are able to navigate around the globe using Earth’s magnetic field or how plants use photosynthesis to harvest sunlight for conversion to chemical energy. All depend on subtle quantum effects that are now coming to light, thereby ushering the topic of quantum biology into CMP. Deoxyribonucleic acid (DNA), the molecule responsible for storage of genetic information in the cells of all living organism, is entrusted with the task of preserving, copying, and transmitting information that are necessary for living beings to grow and function. It is often referred to as the body’s hereditary material as DNA is replicated and transmitted from parents to their offspring. This “molecule of life” was discovered in 1869 by Friedrich Miescher in Tübingen, Germany, who called it “nuclein,” as it was isolated from the nucleus of white blood cells (Dahm, 2005; Thess et al., 2021). It took more than eighty years from that momentous event, to discover that DNA has a right-handed double-helix structure with appropriate base pairing (Watson and Crick, 1953; Klug, 2004). That discovery was so important that it has been compared with the discovery of the atomic nucleus in physics (Frank-Kamenetskii, 1997). Understanding the structure of the atom heralded quantum physics, while understanding of the structure of DNA brought forth the field of molecular biology.

DNA has several remarkable properties that make this molecule a prime candidate for nano-electronic materials (Chakraborty, 2007). These include molecular recognition and the ability to self-assemble via the complementarity of the base sequences on the two strands, which means that DNA can be integrated error-free in current semiconductor technology. DNA can also detect information about its own integrity that can trigger its eventual repair mechanism. All these properties are perfectly suitable for developing nanoscale electronics involving DNA

(Taniguchi and Kawai, 2006). Despite the promise of harnessing biology to realize integrated molecular electronics remains fascinating, much work remains to be done to make it a reality (Braun and Keren, 2004).

Protein molecules play a vital role in all living organisms. They are described as Nature's robots (Tanford and Reynolds, 2001) because for every imaginable task required in a living organism, and for every step of that task, there is a protein designed to carry it out. These proteins are even programmed to know when to turn on or off. Just as the twenty-six letters in the alphabet can spell out hundreds of thousands of words, there are twenty different naturally occurring amino acids that can be combined into many more different proteins than there are atoms in the known universe! Protein's biological function is determined by its unique and native three-dimensional structures that are characteristic of individual proteins (Gomes and Faísca, 2019; Echenique, 2007). The question of how proteins fold to their unique, compact, and highly organized functional states has remained an enduring challenge ("The protein-folding problem") (Chan and Dill, 1993; Dill and MacCallum, 2012; Wolynes and Eaton, 1999). Recently, there has been a tremendous development in this area of research. In November 2020, an AI program called AlphaFold, designed to tackle the problem of protein folding, predicted the three-dimensional structures of almost every protein known to science—about 200 millions in all (Jumper et al., 2021). AlphaFold uses a machine learning methodology to bring together information from preexisting knowledge of protein structures, and other geometric and physical constraints to predict protein structures. While this has been heralded a watershed moment in structural biology (Perrakis and Sixma, 2021), there are many key questions that AlphaFold cannot address yet. These include aspects of protein behavior that cannot be understood from a static structure, such as how proteins respond to their environment or how intrinsically disordered proteins actually are organized. Some authors (Nasser et al., 2021) have likened it to solving a crime story: while AlphaFold presents a snapshot in time, the question about how we get there remains unanswered. Biological systems have developed elaborate mechanisms to ensure that proteins fold correctly, or otherwise, they are detected and degraded before any serious harm can result to the host organism. However, protein misfolding does happen and that misfolding in the cell is linked to an array of diseases, including cancers, cardiovascular disease, type II diabetes, and numerous neurodegenerative diseases, such as Alzheimer's, Parkinson's, and Huntington's disease. NMR spectroscopy has been an important technique to study protein folding where valuable insights are gained into many aspects of the folding process (Jane Dyson and Wright, 1996).

In this Encyclopedia, we strive to present a taste of all the developments in CMP described above (and much more), written by experts in the field. We are keenly aware that many important and interesting topics are not covered here. However, that is not for want of trying. As some authors had rightly pointed out (Hoddeson, 1992): The field is huge and varied and lacks the unifying features beloved of historians, neither a single hypothesis or set of basic equations underpin the field, as in quantum mechanics or relativity theory, nor a single spectacular and fundamental discovery such as uranium fission for nuclear technology or the structure of DNA for molecular biology. CMP owes what unity it has simply to a common concern with solid and liquid materials. This encompasses such a large range of theories and methods that the field resembles a confederation of interest groups rather than a single entity. Clearly, the task of collecting everything in one place is a monumental endeavor, but we do hope that our compilation of a large number of chapters in this five-volume work, covering a broad range of in-depth descriptions of varied phenomena in CMP will be a treasured source of facts and ideas for the community.

It is undeniably true that there would have been no Encyclopedia without the extraordinary contributions of the large number of authors whose valuable time and efforts brought this project to fruition. My sincere thanks to all of them. I also wish to extend my deep appreciation to the staff at Elsevier for their skillful handling of this huge project. The cover image was created by Hong-Yi Chen from National Taiwan Normal University. The image below was created by Elisabetta Collini, one of the authors. My deepest appreciation to them for taking the time to do this work. Finally, my sincere thanks to the Section editors, Vladimir Fomin, Ana Sanchez, Roberto Raimondi, Hideo Aoki, Rudolf Römer, and Robert Blick for the effort they all expended, that has contributed to the success of this venture. Special thanks go to Vladimir Fomin and Ana Sanchez for securing a large share of the chapters and for their enduring help in providing valuable advice and support to bring the project to fruition. Thanks are also due to many of my friends and colleagues, in particular, Michael Coey, Jürg Fröhlich, Sinéad Griffin, Peter Maksym, Eric Vincent, and Jakob Yngvason for their careful and critical reading of the introduction.

Abstract

The discovery of the quantum Hall effect in 1980 triggered a revolution in metrology. As a result, a modified system of units based on natural constants with a fixed value for the von Klitzing constant h/e^2 , where h is the Planck constant and e is the elementary charge, was established worldwide on May 20, 2019. Combined with the Josephson effect, all electrical units today are based on natural constants. Moreover, the quantum Hall effect enabled the kilogram to be defined as an internationally standardized unit of mass based on a fixed value for the Planck constant via the Kibble balance.

Key points

- The discovery of the quantum Hall effect in 1980 was based on experiments that showed the presence of plateaus in the Hall resistance, insensitive to the amount of localized electron states due to disorder.
- High-precision measurements of the quantized Hall resistance performed at various metrology institutes demonstrated the universality of the quantized value.
- A conventional value for the quantized Hall resistance was introduced for metrological applications between 1990 and 2019 (conventional von Klitzing constant).
- The quantized resistance is not affected by the gravitational potential but may have corrections at the 10^{-20} level due to vacuum polarization.
- The CODATA least-squares fit of fundamental constants failed to detect an inexactness of the quantized Hall resistivity with the fundamental constant h/e^2 .
- The revised International System of Units introduced in 2019 with fixed values for the fundamental constants h and e integrates the quantized Hall resistance as a resistance standard into the SI system.
- The electric quantum standard for the resistance (QHE) and voltage (Josephson effect) allows the mass unit kilogram to be defined in terms of the Kibble balance based on a fixed value for the Planck constant h .
- The electrical units farad and henry can be traced back to the von Klitzing constant h/e^2 via the ac quantum Hall effect.
- The parallel and series connection of quantum Hall devices allows resistance standards to be defined with arbitrary values.

Introduction

Modern metrology, the science of measurements, originated from the French Revolution, when the metric system with its prototypes for the meter and kilogram was introduced. The rotation frequency and circumference of the Earth as well as one cubic decimeter of water originally served as references for global units of time, length and mass, respectively. This system was internationally adopted by the Metre Convention in 1875. However, Scottish physicist J.C. Maxwell criticized this development, stating that, "The properties of the earth are not stable enough for a precise definition of the units length, time and mass. The wavelength, frequency and mass of atoms are much more suitable for time independent and stable basic units" (Maxwell, 1870). Maxwell's theoretical objections could not be implemented experimentally with high precision until the 1970s, when both the second and the meter were redefined in terms of atomic properties as follows: The standard ephemeris second based on the Earth's orbit around the Sun was replaced by a fixed value of $\Delta\nu_{\text{Cs}}$, which denotes the transition between the two hyperfine ground states of cesium-133, and the meter was redefined by a fixed value for the wavelength of a special spectral line of krypton-86. However, the finite linewidth and asymmetry of this spectral line were subsequently found to limit the accuracy of this definition of the meter. Consequently, the meter was redefined yet again in 1983 by something that is even more reliable than atomic properties: The value of a fundamental constant. This radical new concept of defining a unit of measure by fixing the value of a fundamental constant became the blueprint for today's International System of Units and is the most important application of the quantum Hall effect (QHE) (von Klitzing et al., 1980).

International system of units (SI units)

The profound industrial importance of electricity, thermodynamics, optics and chemistry requires globally recognized basic units of measure, in addition to the historically most important units of kilogram, meter and second. The International System of Units (SI system) was introduced in 1960 and consists of the seven base units of second, meter, kilogram, ampere, kelvin, mole, and candela (BIPM, SI Brochure, 2019). This system can accommodate an unlimited number of derived units, all of which can be expressed in terms of these seven base units. The 22 most common coherent derived SI units are generally referred to by their own nomenclature, such as ohm for electrical resistance, which is defined in terms of the base units as $1 \Omega = 1 \text{ kg m}^2 \text{ s}^{-3} \text{ A}^{-2}$.

The practical importance of standardized units for global commerce requires that the base units can be reproduced worldwide with high accuracy and that these units remain stable over time. Fundamental constants are best suited to fulfill these requirements. For example, in the late 1800s, Max Planck, who discovered the two fundamental constants known today as the Planck and Boltzmann constants h and k , respectively, also developed units for length, mass, time and temperature based on a combination of fundamental constants. Planck determined that "...with the help of fundamental constants, we have the capability to establish units of length, time, mass, and temperature, which necessarily retain their significance for all cultures, even unearthly and nonhuman ones" (Planck, 1900). Unfortunately, these Planck units with length scales of 10^{-35} m or mass units of the order of 10^{-10} kg could not be obtained with high precision and were therefore not useful for practical applications.

Another 80 years would elapse before the velocity of light was chosen as the fundamental constant in terms of which all base units could be defined in today's International System of Units. With the development of lasers, it became possible to measure the velocity of light with such high precision that this replaced the previous definition of the velocity of light in terms of the meter, which had formerly been defined based on the wavelength of ^{86}Kr . Consequently, the official definition of the meter as the base unit of length was redefined in 1983 "by taking the fixed numerical value of the speed of light in vacuum, c , to be 299,792,458 when expressed in the unit m s^{-1} , where the second is defined in terms of the cesium frequency $\Delta\nu_{\text{Cs}}$ " (BIPM, SI Brochure, 2019). This definition is identical to a fixed value for the velocity of light and launched the incorporation of fundamental constants into today's SI system, which was established worldwide as the new International System of Units on May 20, 2019.

This landmark accomplishment would not have been possible without the discovery of new quantum phenomena. The theoretical prediction of the Josephson effect (Josephson, 1962) and the experimental demonstration by Tsai et al. (1983) of a voltage based on fundamental constants with a reproducibility of 2 parts in 10^{16} paved the way for further applications of fundamental constants in metrology. The US National Bureau of Standards was the first national metrology institute to introduce a Josephson voltage standard (Field et al., 1973). However, it was not possible simply to replace a base unit with this new "quantum volt", meaning that the volt had to be defined as a unit of electricity outside the official International System of Units. Different countries used different values for the Josephson constant $K_J = 2e/h$ in order to replace electrochemical Weston cells with the Josephson effect as their voltage standard. Four different voltage standards with differences of up to 6 ppm were adopted by the US, France, Russia and the rest of the world. Ultimately, however, this changed with the discovery of the QHE and the worldwide introduction of conventional standards for electrical quantum units in 1990 (Quinn, 1989).

Universality of quantized Hall resistance

From the very beginning of the "quantum Hall age", the high precision of the quantized Hall plateaus was the most surprising finding. Experiments performed in 1980 at the High Magnetic Field Laboratory in Grenoble, France, (see Fig. 1) showed for the first time that the Hall resistance under the condition of a fully occupied Landau level agrees with the fundamental value of h/e^2 , where h is the Planck constant and e is the elementary charge, and is insensitive to device properties. This quantization on a macroscopic level was unexpected. The article by Jürgen Weis (2022) in this encyclopedia provides an introduction to this quantum effect within a model of independent charge carriers. More general explanations of the QHE are based on gauge arguments by Laughlin (1981) and topological numbers (Niu et al., 1985; Hastings and Michalakakis, 2015). However, at the time the QHE was discovered, it was assumed that disorder in a device influences the Hall effect and that localized states present in the tails of a Landau level are missing in Hall effect measurements (Aoki and Kamimura, 1977). On the other hand, extensive calculations of the Hall effect in two-dimensional systems by Ando et al. (1975) indicated that impurity bands, separated from a Landau level, do not influence the ideal value of the Hall effect for a fully occupied Landau level. Experimental Hall effect data had been published as early as 1978 (Englert and von Klitzing, 1978; Kawaji, 1978). However, the carrier density for these measurements had always been calibrated on the basis of the gate capacitance and the threshold voltage of the device, but not related to the degeneracy of a Landau level. In addition, the discovery of the QHE in 1980 highlighted that the Hall resistance (calculated directly from the measured Hall voltage and the current through the device) is identical to the resistivity tensor component ρ_{xy} used in theoretical calculations.

The first manuscript to describe the discovery of the QHE was submitted to *Physical Review Letters* and originally entitled "Realization of a resistance standard based on natural constant." It remains today the most important application of the QHE in metrology. Peer reviewer Barry Taylor at the National Bureau of Standards requested that the title be changed to "New method for high-accuracy determination of the fine-structure constant based on quantized Hall resistance" (von Klitzing et al., 1980). This change was justified by the fact that, at the time the QHE was discovered, the uncertainty in demonstrating a resistance in terms of SI ohms via the calculable Thompson and Lampard (1956) capacitor was less than the uncertainty regarding the value of

Fig. 2 Summary of high-precision measurements of fundamental quantized Hall resistance up to 1988, starting with the value of the original publication (von Klitzing et al., 1980). The value for the conventional von Klitzing constant was adopted internationally in 1990 (Quinn, 1989).

the fine-structure constant α . With the introduction of a fixed value for the velocity of light in 1983, however, the inverse fine-structure constant was in fact found to be identical to h/e^2 , apart from the exactly known value for the proportionality constant $2 \epsilon_0 c \equiv (2\pi \cdot 29.9792458)^{-1} \Omega^{-1}$. (Note that the permittivity constant ϵ_0 is no longer a fixed number in the current SI). Ironically, the original title of the manuscript “Realization of a resistance standard...” would have proved more appropriate today.

As shown in Fig. 2, many National Metrology Institutes (NMI) have since confirmed the reproducibility of the quantized Hall resistance measured with various devices (Taylor and Witt, 1989). The stability of this quantum resistor was so high that a time-dependent variation of the ohm (represented by a wire resistor) officially established by the U.S. National Bureau of Standards was measured to have a drift of -0.055 ppm/year (Fig. 3). Different NMIs observed similar variations of the national resistance

standards, originating mainly from strain in the wire. The stability and reproducibility of the quantized Hall resistance was so convincing that, on January 1, 1990, a fixed value for the conventional von Klitzing constant of $R_{K-90} = 25,812.807 \, \Omega$ was adopted worldwide for all resistance calibrations based on the QHE (Quinn, 1989). At the same time, a global value for the conventional Josephson constant was fixed, which resulted in very reproducible electrical units outside the official SI units. Delahaye and Jeckelmann (2003) published a guideline that describes the tests and precautions necessary for reliable precision measurements of the quantized Hall resistance with an uncertainty of only a few parts in 10^9 , according to the official recommendation of the Consultative Committee for Electricity and Magnetism (CCEM).

Is the quantized Hall resistance identical to h/e^2 ?

High-precision comparisons obtained using different quantum Hall devices, the results of which included not only the integer QHE but also the fractional quantum Hall effect (FQHE) and the quantum anomalous Hall effect (QAHE), demonstrated the universality of quantized Hall resistance up to an experimental uncertainty of only a few parts in 10^{11} as shown in Fig. 4. However, this does not prove that the quantized resistance is identical to h/e^2 without corrections. Taylor and Cohen (1991) applied a least-squares adjustment of all experimental data to determine the best value for the fine-structure constant (excluding QHE data) to establish that better consistency is achieved if the measured quantized Hall resistance is about 0.06 ppm greater than the corresponding h/e^2 value. However, the 2006 CODATA least-squares adjustment of fundamental constants could not identify a correction for the relation $R_K = h/e^2$ within the uncertainty margin of 2 parts in 10^8 . The metrology community accepted the conclusion that there is no experimental evidence for the inaccuracy of $K_J = 2e/h$ nor that of $R_K = h/e^2$ (Mohr et al., 2008).

Another test to verify the correct description of electric quantum units by fundamental constants resulted from the development of electron pumps (Pekola et al., 2013). Such pumps allow the controlled charging and discharging of a quantum dot with one electron leading to a quantum current $I = e \cdot f$, where f is the pumping frequency, which can be calibrated from the atomic clock. The combination of an electron pump with a quantum Hall resistor and a Josephson voltmeter (quantum metrology triangle QMT)

Fig. 4 Universality of quantized Hall resistance. Comparison between different two-dimensional electron systems including fractional quantum Hall effect (FQHE) and quantum anomalous Hall effect (QAHE) (Hartland et al., 1991; Schopfer and Poirier, 2007; Janssen et al., 2012; Woszczyzna et al., 2012; Ahlers et al., 2017; Götz et al., 2018; Okazaki et al., 2022).

showed no inconsistency at 1 ppm (Scherer and Camarota, 2012). The accuracy of these experiments is limited by the electron pumps, which produce relatively small currents of approximately 100 pA. Advanced QMT experiments will reduce the uncertainty by about one order of magnitude (Scherer and Schumacher, 2019) and will enhance confidence in our theoretical understanding and the consistency of the quantum electrical effects.

Some theoretical publications have discussed various possible corrections of the relation $R_K = h/e^2$. Even the finite width W of a Hall device in relation to the diameter of the classical cyclotron orbit could contribute to a correction (Shapiro, 1986). However, experiments using devices with different widths ranging from 1 mm to as small as 10 μm showed no width dependence of the quantized Hall resistance within the margin of experimental uncertainty of 1 part in 10^9 (Jeanneret et al., 1995).

Other theoretical publications have discussed the influence of gravity on the QHE. For example, Hehl et al. (2004) found no influence of the gravitational field if it is perpendicular to two-dimensional electron gas (2DEG), but that an additional electric field due to gravity does exist if the gravitational field is parallel to the Hall field. This was analyzed in detail by Hammad et al. (2020). The mere force of the Earth's gravitational field on the electron mass should lead to an electric field of $0.55 \times 10^{-10} \text{ V m}^{-1}$, which is about 13 orders of magnitude less than the Hall field used for high-precision QHE measurements. So far, no experimental data has been published that evaluates the influence of gravity on the quantized Hall resistance. Nevertheless, the gravitational field is not expected to have an effect as long as the gravitational potential does not change within the plane of the two-dimensional electronic system.

Penin (2009) took a quantum electrodynamic (QED) approach to predict a small correction to the von Klitzing constant due to vacuum polarization in strong magnetic fields with the following result:

$$R_K \approx h/e^2 [1 - 10^{-20} \cdot (B/10 \text{ T})^2].$$

Such a correction of approximately 1 part in 10^{20} under a typical magnetic field of 10 T in QHE experiments is negligible for metrological applications of the QHE, meaning that all measurements of the quantized Hall resistance are consistent with the equation $R_K = h/e^2$.

Integration of electrical quantum units into the official SI system

In 1988, the least-squares adjustment of all measurements of the quantized Hall resistance yielded a value of $R_K = 25,812.807 (5) \Omega$ (Taylor and Witt, 1989). The uncertainty margin of some 2 parts in 10^7 was dominated by the uncertainty inherent in expressing ohm in terms of SI units. As the reproducibility of the QHE resistance was significantly greater, a fixed conventional value of $R_{K-90} \equiv 25,812.807 \Omega$ was introduced in 1990 for metrological applications. This led to international uniformity of all resistance calibrations with uncertainties of less than 10^{-8} . However, such calibrations were outside the official SI system, and more accurate measurements of h/e^2 showed an increasing discrepancy between the von Klitzing constant $R_K = h/e^2$ and the conventional value of R_{K-90} as shown in Fig. 5. Similar discrepancies appeared between the Josephson constant $K_J = 2e/h$ and the conventional value of $K_{J-90} \equiv 483,597.9 \times 10^9 \text{ Hz V}^{-1}$. To prevent quantum units from diverging ever further from SI units, the idea was proposed to integrate the von Klitzing constant and the Josephson constant into the International System of Units. However, this would mean abandoning the definitions of two established base units. The breakthrough solution came from Steiner et al. (2005), who presented high-precision measurements with a watt balance (known since 2017 as the Kibble balance). This created the capability to trace the mass unit of the kilogram back to the Planck constant h with sufficient accuracy. In that experiment, the mechanical force of a mass is compensated by the electrical force of a current in a magnetic field, calibrated in accordance with electrical quantum standards. Hence, electrical quantum units gave way to a new definition of the kilogram based on the fundamental constant h .

Fig. 5 Recommended CODATA values for the von Klitzing constant $R_K = h/e^2$.

Evidence that the kilogram artifact at the BIPM was not stable in time (Girard, 1994) supported the idea of replacing the kilogram and introducing a new system of units (Mills et al., 2005; Schlamminger and Haddad, 2019). Establishing this revised system was the focus of a historic discussion at the Royal Society in London in 2005 (Quinn and Burnett, 2005). With fixed values for e and h , not only could the base units of ampere and kilogram be related to fundamental constants, but the Josephson and von Klitzing constants could also be integrated into the revised International System of Units. The contribution of C. Borde (2005) at that discussion made it clear that electric metrology is in the midst of a paradigm shift that will play a key role for the entire field of metrology.

A revised international system of units was proposed by Mills et al. (2006), but 12 years would elapse before participants at the 26th General Conference on Weights and Measures voted unanimously to implement a new International System of Units as of May 20, 2019. The fixed values of the constants of nature, which form the basis of today's modified International System of Units, are summarized in Fig. 6. Practical realizations of the SI units have since been published (BIPM, SI Brochure, 2019), which, for example, are defined for the electrical unit ohm as follows:

The ohm is the electric resistance between two points of a conductor when a constant potential difference of 1 volt, applied to these points, produces in the conductor a current of 1 ampere, the conductor not being the seat of any electromotive force. The ohm can be defined by using the QHE in a manner consistent with the CCEM Guidelines (Delahaye and Jeckelmann, 2003) and using the value of the von Klitzing constant $R_K = 25,812.8074593045 \Omega$.

With this recommendation, issued some 40 years after the discovery of the QHE, the vision of the original manuscript describing the application of this quantum effect, which, ironically enough, was rejected, has come to fruition.

With the discovery of graphene as an ideal two-dimensional electron system, it has become simpler to apply the QHE as a resistance standard. In particular, graphene on SiC (epigraphene) exhibits many advantageous features compared to those of GaAs heterostructures, a well-established material. Ribeiro-Palau et al. (2015) demonstrated that the Hall resistance can be accurately quantized to within 1×10^{-9} over a 10-T-wide range of magnetic field starting as low as 3.5 T. Moreover, the same precision can be achieved at temperatures as high as 10 K and device currents up to 500 μ A. Further research is needed to optimize epitaxial graphene for quantum Hall applications (Meng et al., 2022).

A special feature of the QHE is that not only the four-terminal Hall resistance but also the two-terminal resistance between any two contacts at the boundary of a QHE device has the quantized resistance. Errors due to finite contact resistance can be reduced to a negligible value by the multiple-series connection scheme (Delahaye, 1993). This created the possibility to establish quantum Hall array standards (QHARS) by combining QHE devices in parallel and in series with quantized resistances at arbitrary levels (Poirier et al., 2004). A scheme for decade-value standards in the range from 100 Ω to 1 M Ω has been presented by Oe et al. (2013). Comparisons of two epigraphene QHARS with 138 devices in parallel (array resistance $R \approx 109 \Omega$) showed a relative deviation of only 3 parts in 10^{11} and, compared to a single quantum Hall device, was in agreement with the target value of $R_K/276$ within the uncertainty of 2 parts in 10^{10} (He et al., 2022). To eliminate lead resistances, the contacts and interconnects were made of NbN superconducting films, which can support currents on the order of 10 mA at 5 T and 2 K.

Extending the application of the quantized Hall resistance as the primary resistance standard results from the ac QHE in the frequency range from 50 Hz to 20 kHz. This allows direct measurements of impedances (Schurr et al., 2007; Ahlers et al., 2009) with uncertainties of less than 10^{-8} . Calibration of capacitances (Schurr et al., 2009; Schurr and Lee, 2022) in the range from 10 nF to 10 pF and inductances (Overney and Jeanneret, 2010) in the range from 1 μ H to 10 H were traced back to the von Klitzing constant.

By integrating the conventional electrical quantum units used since 1990 into the International System of Units, the electrical units ohm, farad and henry changed discontinuously on May 20, 2019, by a fractional amount of 17.793×10^{-9} . The corresponding jump for the Josephson volt was nearly four times greater. Such discontinuities for units of measure will never happen again as long as fundamental constants remain constant. Having said that, discussions of possible changes in fundamental constants with time are very important and will focus on the fine-structure constant, which depends on the most important fundamental constants h , e , and c . This has the advantage of being a dimensionless constant independent of units. The most accurate measurements of this constant show that the change is less than 1 part in 10^{17} per year (Safronova, 2019). Possible variations of the fundamental constants at this level are insignificant in metrology for the foreseeable future.

Quantity	Symbol	Numerical value	Unit
^{133}Cs hyperfine transition frequency	$\Delta\nu_{\text{Cs}}$	9,192,631,770	Hz
Speed of light in vacuum	c	299,792,458	m s ⁻¹

Conclusion

The QHE plays a central role in metrology and was crucial for updating the International System of Units based on constants of nature. Even if a complete theory of the QHE for real devices with finite dimensions, electrical contacts, uncontrolled disorder and in the presence of relatively high bias currents has not yet been developed, experiments have demonstrated the reliability of this quantum effect for practical applications. The universality of the quantized Hall resistance has been demonstrated to at least 10 digits, and all high-precision experiments agree with the theoretically predicted value of $R_K = h/e^2$ for the quantum Hall plateaus within the experimental uncertainty of 2 parts in 10^8 . The quantized Hall resistance has been officially adopted as a primary realization of the resistance unit ohm. Arrays of quantum Hall devices are used for quantized resistances with arbitrary values in the range from $100\ \Omega$ to $10\ \text{M}\Omega$. Primary realizations of the electrical units farad and henry are possible with the QHE under ac conditions. The development of an electronic kilogram, where the QHE together with the Josephson effect allowed the mass unit to be defined based on a fixed value for the Planck constant h , accelerated the adoption of today's International System of Units. Fig. 7 shows the official logo of this new system that illustrates the relationship to historically introduced base units.

Abstract

We present the basic principle of the pulse-driven AC Josephson Voltage Standard, also called “Josephson arbitrary waveform synthesizer” (JAWS). The JAWS is suitable for generating quantized high-precision and arbitrary waveforms in the time and frequency domain with extremely high spectral purity. A brief overview of the fabrication technology for highly integrated JAWS circuits with more than 50,000 junctions per chip will be described. This includes the stacked junction technology with up to 5-stacked junctions. New approaches designed to further increase the output voltage and to simplify the experimental setup are the on-chip power dividers and the optical pulse drive for the JAWS. Some applications of the JAWS that have significant benefits for quantum AC voltage metrology will be presented. Within international research projects, PTB’s JAWS chips have been distributed to NMIs in the Netherlands, the United Kingdom, Norway, Italy, Finland, Turkey, Russia, China and Argentina. The technology transfer from PTB to the Supracon company for commercialization purposes has also been initiated to make JAWS available to other NMIs, to calibration laboratories and to industry in the near future.

Key points

- Basic principle of the pulse-driven AC Josephson Voltage Standard (JAWS)
- Design of integrated circuits for JAWS
- Key parameter of JAWS: calculable and arbitrary waveforms, quantum precision
- Circuit fabrication: Nb based thin film and stacked junction technology, fabrication yield
- Experimental setup
- Optical pulse-drive and on-chip power divider
- Applications in Voltage Metrology
- Conclusion

Introduction

This chapter provides an overview of the fundamental principles, practical realization, features and chip design of the AC Josephson voltage standard. To define the electrical units via electrical quantum metrology; the Ohm (quantum Hall effect), the Volt (Josephson effect) and the Ampere (single-electron transport) is one of main tasks of Physikalisch-Technische Bundesanstalt (PTB). The PTB (PTB, 2022) is the national metrology institute of the Federal Republic of Germany. The first such institute in the world, PTB was founded in Berlin as the “Physikalisch-Technische Reichsanstalt” (PTR) in 1887 by Hermann von Helmholtz (its first president) and Werner von Siemens to serve as an interface between science, industry and legal metrology. After World War II, the institute was re-built in Berlin and gained a new, second site in Braunschweig, which was housed in a former research facility. In accordance with the new form of government in Germany established after World War II, the former “Reichsanstalt” was designated “Bundesanstalt” in 1950. PTB is the sole (and thus the highest) authority on the correct and reliable measurements of physical units and forms part of the Federal Ministry for Economic Affairs and Climate Action in Germany. PTB has around 1900 employees and an annual budget of some 200 million euros. Over the years, its advisory board members have included 10 Nobel Prize winners – among them Albert Einstein, Max Planck, Gustav Hertz, Max von Laue and Klaus von Klitzing.

The so called “Weston cell,” which was previously the electrical voltage standard beginning in 1911, achieved an DC output voltage of about 1 V and precision of about 10^{-6} . This standard was replaced in the 1980s with DC Josephson voltage standards of 1 V/10 V, whose precision was better than 10^{-9} . An AC quantum voltmeter (AC-QVM) based on programmable Josephson voltage standard (PJVS) chips (up to 10 V) was also developed at PTB. Via technology transfer between PTB and the Supracon company (Supracon, 2022), this voltage standard was made commercially available to national metrology institutes (NMIs) and industry worldwide. The AC-QVM only allows waveforms approximated stepwise (i.e., it is only nominally an AC voltage standard). To overcome this issue, a pulse-driven Josephson voltage standard was proposed by NIST (Benz and Hamilton, 1996) and developed at NIST and PTB. This AC Josephson voltage standard is often referred to as the Josephson arbitrary waveform synthesizer (JAWS).

In the following section, we will introduce the fabrication of JAWS circuits in PTB’s Clean Room Center via a sophisticated thin-film technology based on Josephson junction properties and stacked-junction technology. The experimental setup used and the most recent developments concerning further improvements to the JAWS will also be discussed, including on-chip power dividers and optical pulse drives. Finally, examples will be given of JAWS applications in electrical quantum metrology where these applications were developed and tested at PTB in close cooperation with our research partners from several NMIs, as well as their impact within the international community.

Fundamental elements of the JAWS

The basic principle of JAWS is as follows: a current pulse with a time-dependent pulse-repetition frequency $f_p(t)$ transfers N flux quanta Φ_0 through M Josephson junctions (Benz and Hamilton, 1996). The signal voltage $V(t)$ in pulse-mode operation can be calculated via the Josephson equation, i.e.,

$$V(t) = N \cdot M \cdot \Phi_0 \cdot f_p(t) \quad (1)$$

According to this equation, a time-dependent voltage, which is quantized at all times, is generated at the junction series array output leads, because only flux quanta $\Phi_0 = h/2e$ (h is Planck’s constant and e the elementary charge) are transferred and N and M are integer numbers. The frequency $f_p(t)$ is very well defined by precise knowledge of the time t . The JAWS delivers quantized arbitrary waveforms, when properly biased.

The signal output voltage (RMS) can be obtained from a slight modification of Eq. (1):

$$V_{\text{signal}} (\text{RMS}) = A_{\Sigma\Delta} \cdot N \cdot M \cdot \Phi_0 \cdot f_{\text{clock}}, \quad (2)$$

where $A_{\Sigma\Delta}$ is the sigma-delta ($\Sigma\Delta$) code amplitude (details on which are provided below), i.e., a pre-factor in the range $0 < A_{\Sigma\Delta} < 1$ (Schreier and Temes, 2005).

The signal frequency f_{signal} can easily be calculated from

$$f_{\text{signal}} = T_{\Sigma\Delta} \cdot f_{\text{clock}} / L_{\Sigma\Delta}, \quad (3)$$

where $T_{\Sigma\Delta}$ is the number of signal periods in the sigma-delta coded waveform, $L_{\Sigma\Delta}$ is the length of the sigma-delta code, and f_{clock} is the clock frequency of the pulse pattern generator (PPG), which delivers high-frequency pulses to the Josephson array.

For JAWS applications, SNS-type Josephson junctions are used (S = superconductor, N = normal conductor). SNS junctions provide a non-hysteric current-voltage characteristic under microwave irradiation. In pulse-mode operation, Shapiro steps are selected by adjusting the pulse amplitude (see Fig. 1). Large Shapiro steps are generated for all pulse repetition frequencies below the characteristic frequency f_c of the SNS junctions: $f_p \leq f_c$ (Benz and Hamilton, 1996). The maximum pulse-repetition frequencies most frequently used for the JAWS are the 15 GHz return-to-zero pulse, which is typically limited by the maximum clock frequency of commercially available PPGs. This corresponds to a maximum data rate of 30 Gbit/s.

Because a flux-quantum provides only a very small voltage ($\Phi_0 \approx 2 \mu\text{V}/\text{GHz}$), many Josephson junctions must be implemented in a series array in order to achieve practicable large output voltages (e.g. 5000 junctions to achieve 100 mV RMS output voltage at

Fig. 1 Current-voltage characteristics of SNS junctions without and with pulse irradiation.

15 GHz clock frequency). Since the pulse repetition frequency is not constant in time ($f_p(t) \neq \text{const.}$), the availability of a broadband circuit design is an important precondition for operating the JAWS properly.

Fig. 2 shows a typical JAWS circuit layout. Two independent JAWS arrays are integrated on a $10 \text{ mm} \times 10 \text{ mm}$ silicon chip. The enlarged picture on the right illustrates that the Josephson junctions are embedded in the center line of a coplanar waveguide (CPW). The CPW is matched to a 50Ω impedance that corresponds to the impedance of the complete JAWS setup (details on which are provided below). A 50Ω termination (load) is realized at the end of the array to prevent pulse reflections. A CPW taper at the HF pulse input side of the chip is implemented to enable a proper Al wire bond of the chip to a printed circuit board (PCB) carrier. At the current input and voltage output leads, LCR filters (Watanabe et al., 2006) are integrated to prevent the propagation of the input pulses along these lines, as this would lead to distortions in the frequency spectrum of the synthesized waveforms.

The practical realization of the JAWS, i.e., the way in which an arbitrary waveform is quantized with the JAWS chip, is sketched in Fig. 3. Here, we use a sine waveform for the sake of simplicity. Such a waveform is advantageous because, in an ideal case, there will only be one fundamental tone (the signal frequency) in the frequency spectrum, and no higher harmonics will appear. By means of a higher-order sigma-delta modulation (Kiehl et al., 2009) ($\Sigma\Delta$ modulation), this analog waveform is digitized into a bit pattern

Fig. 2 Example of JAWS chip circuit layout.

Fig. 3 Sketch of the practical realization of quantized waveforms with JAWS.

($\Sigma\Delta$ code) which has the restricted values $+1$, 0 and -1 . The aim of a high-quality Sigma Delta modulation is to ensure that the fast Fourier transform (FFT) of this Sigma Delta code is highly pure on the spectral side, that it has a very low noise floor and a quantization noise shifted to very high frequencies (>1 MHz) far beyond the desired signal frequency. At PTB, a second-order modulator with integrated feedback is typically used, i.e., a CIFB modulator topology (CIFB: cascade of integrators with integrated feedback) (Schreier and Temes, 2005). A stable $\Sigma\Delta$ modulation is realized if $A_{\Sigma\Delta} < 1$. This bit pattern is stored in the memory of the fast PPG. Typical $\Sigma\Delta$ code lengths range from around 2 Mbit to 512 Mbit depending on the desired signal frequency and other properties of the waveform. The ternary pulses ($+1$, 0 , -1) of the PPG are transferred via suitable HF cables to the JAWS chip operating at 4 K. In the Josephson junction array, each input pulse generates a flux pulse. At the array output leads, the quantized waveform can be detected and fed out to a room temperature (300K) environment to be used for applications or further spectral analysis.

Ultimately, the JAWS can be considered a quantum standard characterized by these key features:

- high-precision quantized AC voltage source,
- synthesis of arbitrary waveforms (frequency or time domain),
- excellent spectral purity (signal-to-noise ratio SNR > 130 dBc),
- no drift,
- low noise,
- wide frequency bandwidth (a few Hz, including 0 Hz, up to the MHz range).

These considerable advantages over semiconductor-based waveform synthesis make the JAWS highly suitable for metrological applications. JAWS signals can be synthesized in a very wide frequency range from a few Hertz up to the Megahertz range and DC voltages are possible too. We will briefly explain the relevance of these features by presenting some waveform examples and data.

Fig. 4 shows the frequency spectra of two sine waveforms to demonstrate the concept of “calculable” waveforms. The first waveforms have a signal frequency of 1111.11 Hz and a signal voltage of 111.11 mV RMS, yielding an “11 $\times$ 1” sine. This figure also demonstrates spectral purity: no higher harmonics are above the noise floor and the signal-to-noise ratio is about 123 dBc, which corresponds to the dynamic limit of the spectrum analyzer used. The small distortion peak at about 3.3 kHz is related only to the spectrum analyzer (Benz et al., 2015), whereas the JAWS chip is well quantized, while operating in the quantum-locked state (Burroughs et al., 2005) with sufficient operation margins. The second spectrum shows a similar waveform, i.e., a “1 to 9” sine. Here, the signal frequency is 1234.5 Hz and the signal amplitude is 67.89 mV RMS.

Other frequency spectra (Fig. 5) show the wide frequency range of the JAWS. Using an array of 12,000 junctions, different signal frequencies of spectrally pure sine waveforms from 10 Hz to 1 MHz were synthesized at a signal amplitude of 100 mV RMS.

Finally, two arbitrary waveforms are presented in Fig. 6. On the left, an arbitrary signal in the frequency domain is shown: a multitone waveform (132 tones) with different signal amplitudes that resembles the word “JAWS” (Behr et al., 2012). On the right,

Fig. 4 Frequency spectra of two example sine waveforms.

Fig. 5 Frequency spectra of different sine waveforms from 10 Hz to 1 MHz.

Fig. 6 Left: arbitrary frequency domain waveform, right: arbitrary time domain waveform.

an arbitrary time-domain waveform illustrates an ideal heart-beat signal. Both examples demonstrate that virtually any arbitrary waveform, and even complex waveforms, can be created.

To confirm the quantum precision of the JAWS, we performed a direct comparison between the JAWS and the PTB AC-QVM for voltages at 1 V RMS and 250 Hz. Excellent agreement was achieved: $V_{\text{JAWS}} - V_{\text{QVM}} = (3.5 \pm 12) \text{ nV}$ (Behr et al., 2015). This comparison was a highlight paper of the journal “Metrologia” in 2015. This direct comparison achieved even better agreement for DC voltages at a 1 V peak: $V_{\text{JAWS}} - V_{\text{QVM}} = (0.3 \pm 04) \text{ nV}$ (Behr and Kieler, 2020). This quantum precision is a precondition for any application in voltage metrology. In (Kieler et al., 2017), we were able to make 16 arrays operate in parallel with a total number of 162,000 junctions, achieving an output voltage of 2.25 V RMS. This represented an important milestone toward achieving 7 V RMS with the JAWS in order to increase the number of metrological applications possible. Other current JAWS developments include simplifying the experimental setup in order to lower the overall costs of a complete JAWS system, increasing the number of applications to provide greater benefits to NMIs and industry and initiating the technology transfer necessary to make the JAWS commercially available.

JAWS technology

JAWS circuits are fabricated at PTB’s Clean Room Center (class ISO 5). This clean room is fully equipped for the high-quality fabrication of superconducting circuits based on Nb as a superconductor. The main fabrication tools used in this process are a cluster sputtering system for highly reproducible deposition conditions and an electron-beam lithography system for high alignment precision and fast prototyping (thus rendering the use of masks unnecessary, in contrast to UV lithography). Previously, SNS Josephson junctions with HfTi as a normal-metal barrier were used at PTB for JAWS applications (Kieler et al., 2007a; Kieler et al., 2007b; Kieler et al., 2009). These junctions were characterized by a high critical current density in the range of $>50 \text{ kA/cm}^2$. Consequently, the junction size was limited to the sub- μm range. For large arrays, we observed that these junctions were not suitable because heating effects caused by the high current density degraded the properties of the junctions. This issue prompted the use of SNS Josephson junctions with $\text{Nb}_x\text{Si}_{1-x}$ as the normal-metal barrier material (Baek et al., 2006; Kieler et al., 2013a). The SNS

multilayers are deposited in the cluster sputtering system, which consists of six chambers in total and is fully automatic. The $\text{Nb}_x\text{Si}_{1-x}$ barrier is deposited in a co-sputter process from two targets (Nb and Si) onto the rotating 3-in. Si wafer. The homogeneous and reproducible deposition conditions are very important to achieve a low parameter spread of the junction's characteristic properties. These junction properties can be adjusted nearly independently over a wide range by choosing the composition x and the thickness d as shown in Fig. 7, where the critical current density is plotted against the characteristic voltage. The Josephson junction operation frequency can be tuned from about 1 GHz to 150 GHz (and beyond). An x of about 0.2 and a thickness d of about 30–40 nm are typical parameters in JAWS applications.

Such SNS junctions are advantageous in that they can be deposited and patterned in junction stacks, which increases the integration density of the JAWS circuits. To manufacture 5-stacked junctions, a 12-layer multilayer is first deposited *in-situ* in the cluster system, cf. Fig. 8. On top of a thermally oxidized wafer, a thin etch stop layer made of Al_2O_3 is deposited first to prevent the plasma from etching into the SiO_2 . The 5-stacked junctions consist of 6 Nb and 5 $\text{Nb}_x\text{Si}_{1-x}$ layers. The resulting total layer structure is as follows: $\text{Si}/\text{SiO}_2/\text{Al}_2\text{O}_3/\text{Nb}/\text{Nb}_x\text{Si}_{1-x}/\text{Nb}/\text{Nb}_x\text{Si}_{1-x}/\text{Nb}/\text{Nb}_x\text{Si}_{1-x}/\text{Nb}/\text{Nb}_x\text{Si}_{1-x}/\text{Nb}/\text{Nb}_x\text{Si}_{1-x}/\text{Nb}$. A modified “window” process was developed at PTB (Kielar et al., 2021) to fabricate up to 5-stacked Josephson junction series arrays with a high yield. To achieve this, the thicknesses of the Nb and SiO_2 resists were increased. Additionally, the SiO_2 was deposited not only by means of PECVD, but also in a thin ALD layer (before PECVD) to ensure perfect edge coverage for the tall junction stacks. This was necessary to avoid shorts at the uppermost junctions in the stack, which had been problematic without ALD. A soft CMP step was also introduced for the SiO_2 layer to ensure smoothness of the surface before deposition of the Nb-wiring layers. This was done to prevent this superconducting layer from having a weak current capability due to poor edge coverage.

The complete fabrication process consists of six main fabrication steps. First, the Josephson junctions are defined by high-rate RIE-ICP with SF_6 (reactive ion etching with inductive coupled plasma); here, the junction sidewall angle is nearly 90 degrees. This ensures a small parameter spread from one junction floor to the next. Second, the Nb base electrode, which is the lower wiring electrode, is patterned. Third, electrical isolation takes place via atomic layer deposition (ALD) and plasma enhanced chemical vapor deposition (PECVD) SiO_2 and the contact windows on top of each junction stack are opened by via RIE-ICP with CHF_3 . Fourth, additional deposition and patterning of the Nb wiring electrode take place via RIE-ICP. Fifth, deposition takes place for AuPd on-chip resistors for impedance matching of the CPW and the on-chip filters by means of a “lift-off” process. Finally, the wire-bond pads are opened by via RIE-ICP to establish contact between the chip and an appropriate PCB carrier. The total process involves 16 layers and about 40 fabrication steps. The clean room cycle time for two wafers is about 3 weeks. More details about this process can be found in (Kielar et al., 2021) for 3-stacked junctions; this process is similar to the modified 5-stacked junction process

Fig. 7 Critical current density vs. characteristic voltage of SNS junctions with a $\text{Nb}_x\text{Si}_{1-x}$ barrier.

Fig. 8 Multilayer sequence of 5-stacked SNS junctions with $\text{Nb}_x\text{Si}_{1-x}$ barriers deposited *in situ*.

Fig. 9 Cross-section SEM image of a JAWS array with 5-stacked Josephson junctions.

presented in (Kieler et al., 2015). Fig. 9 shows a cross-section SEM image of a JAWS array with 5-stacked Josephson junctions. In this picture, we can clearly recognize the steep junction stacks as required. For the stack on the right, a small under-etch into the stack can be seen. This may be the reason for the slight increase in the parameter spread of the critical current. Compared to the total junction area of $4.4 \mu\text{m} \times 13.6 \mu\text{m}$, this effect is small enough to ensure a high-quality current-voltage characteristic (IVC). Due to the relatively thick layers combined with long etching times and resist problems, we observed large Nb fence structures (also visible in Fig. 9) that mainly consist of residues of the photo resist and nonvolatile etch products; however, these fence structures did not negatively impact the operation of the JAWS circuits.

Fabricating the highly integrated circuits of JAWS chips, which have many thousands of Josephson junctions, requires a high yield of the functional junctions and a low junction parameter spread. Some information on 3-stacked junctions taken from the wide range of available data will be presented below. The critical current density distribution on a 3-in. wafer shows a deviation of 4.6% from the mean value, which is acceptable for functional JAWS arrays with sufficiently wide operation margins in pulse operation mode. We analyzed the data for 200 arrays that had been fabricated on 20 wafers with a minimum junction count of $N = 5000$ in each array. This corresponded to a total junction count of $N = 1,600,000$. Only 48 junctions were defective in the sense that the junction were shorted. This is equivalent to a junction yield of 99.997%, which is more than sufficient for our needs. Clearly, the shorted junctions fail to contribute to the IVC as they are “missing” in Shapiro steps. However, the circuit itself is still functional and can be used for JAWS applications, as the signal voltage levels can be adjusted by choosing the $\Sigma\Delta$ code amplitude and the clock frequency. Because these two parameters can be selected with arbitrary precision, there are no limits to the exactness with which the desired signal amplitudes can be adjusted. In contrast to PJVS, the characteristic voltage of a junction does not restrict the voltage resolution of JAWS. Voltage values far below the characteristic voltage can be tuned (see “calibration of nanovoltmeters” in the “Applications” section).

For the 5-stacked junction arrays, the database available is smaller but allows spreads and yields to be estimated. Measuring 28 arrays from two wafers yielded the following data for the spread of the critical current:

1. intra-array: 2.4%
2. intra-wafer: 3.6%
3. inter-wafer: 6.9%

This data is acceptable for our purposes. The intra-wafer uniformity of the critical current density was determined for one of the 5-stacked junction wafers (3-in.): $(6.66 \pm 0.07) \text{ kA/cm}^2$. Before we implemented ALD into the process, this yield was very poor. By analyzing the data from 58 arrays located on eight wafers, we realized that, on seven wafers, the upper floor of the stack was systematically shorted completely. The reason for this was insufficient edge coverage of the PECVD SiO_2 at the top edge of the high pillar, where notches occurred. Only on one wafer were the junctions not shorted. Here, we measured a junction yield of 99.88%. Ever since the implementation of ALD, we have analyzed the data from 28 arrays on two wafers. No stacks were shorted and only 53 out of 440,000 junctions were “missing,” corresponding to a junction yield of 99.99%; this result is slightly lower than that of 3-stacked junctions but still very good.

Realizing such 5-stacked junction technology entails significant benefits, as we can synthesize an output voltage of 1 V RMS (2.83 V peak-peak) with four arrays integrated on only two chips instead of eight arrays on four chips (Kieler et al., 2015). The frequency and time domain of a sine waveform generated using 60,000 junctions at 500 Hz is shown in Fig. 10.

JAWS Setup

At PTB, eight JAWS systems are used for different applications. Fig. 11 shows the eight-channel JAWS setup. Using this setup, 1.5 V RMS can be synthesized with 93,000 junctions arranged on 8 arrays (i.e., four chips). These four chips are mounted on four specially designed PCBs made of Rogers3006 (Kieler et al., 2013b). These PCBs are arranged in a cryoprobe, as shown in the upper inset, for operation in a liquid helium dewar at 4 K. An eight-channel PPG (Sympuls) that provides ternary pulses, an eight-channel bias device and a spectrum analyzer (PXI 5922, National Instruments) are the main components of the supply electronics for operation

Fig. 10 Frequency and time domain of a sine waveform at 1 V RMS and 500 Hz synthesized with two chips and 60,000 junctions.

Fig. 11 Photograph of the eight-channel PTB JAWS setup. The inset shows details of the cryoprobe with mounted JAWS chips.

of JAWS circuits. To control the whole system and perform the measurements, customized software (made with Labview) was programmed.

In 2013, we also demonstrated how JAWS circuits can be operated in a pulse-tube cryocooler (Kieler et al., 2013b), cf. Fig. 12 (left). For potential users of JAWS, this is a significant advantage, as it allows the liquid helium infrastructure to be circumvented completely. Modern cryocoolers require only a few hours to cool down, are easy to use and require no or only minimal maintenance work. A second cryocooler is designed for daily use for JAWS applications in the impedance bridge (see Section “Applications”), cf. Fig. 12 (right) (Bauer et al., 2017). A third cryocooler will be installed in the near future to shorten the distance between the JAWS chip at 4 K and 300 K from about 1.2 m to about 0.3 m. This will reduce the uncertainty at high signal frequencies in the range of 100 kHz up to 1 MHz (Brom et al., 2016).

Optical pulse drive and on-chip power divider

Very recently, an optical pulse drive for the JAWS was developed in a collaborative effort between PTB and NPL, JV and the University of South-Eastern Norway (USN) (Kieler et al., 2019; Ireland et al., 2017; Bardalen et al., 2017; Bardalen et al., 2018; Ireland et al., 2019; Karlsen et al., 2019; Bardalen et al., 2020; Karlsen et al., 2020; Herick et al., 2020). Considerable effort was

Fig. 12 Photographs of two JAWS setups operated with pulse-tube cryocoolers from Oxford Instruments (left) and TransMIT (right).

Fig. 13 Schematics of “electrical” vs. “optical” JAWS setup.

undertaken by our partner institutions to establish a reliable and robust PD packaging technology with a high yield. The aim of these developments was to create a low-cost solution for the parallel operation of many JAWS arrays by operating fast photodiodes (PD) at 4 K close to the JAWS arrays. Another advantage is that, by using optical fibers (instead of semi-rigid cables), less noise will be introduced – specifically, noise at high signal frequencies in the MHz range. Fig. 13 shows a simplified scheme of the “electrical” JAWS setup vs. the “optical” JAWS setup (Kiehl et al., 2019). For this application, we used high-performance InGaAs PD from Albis:

- dimensions: $350\ \mu\text{m} \times 350\ \mu\text{m}$
- integrated backside lens → suitable for flip-chip bonding
- speed 28 Gbit/s
- wavelength 1310 nm

In a typical JAWS setup at PTB, the electrical pulses are delivered by a PPG and transmitted by an HF coaxial cable about 1.5 m long from the PPG output to the cryoprobe head. The cryoprobe contains a 1.2 m semi-rigid HF coaxial cable to further transfer the pulses to the K-type connectors at the PCB carrier, where the JAWS chip is mounted at 4 K. This electrical pulse transmission is replaced by an optical pulse drive. The pulse pattern is again provided by the PPG and electrically transferred to the RF modulator driver (RF-MD), which serves as an amplifier for the electrical pulses. The amplified pulses are transferred electrically to the Mach-Zehnder Modulator (MZM). The MZM is a LiNbO₃-based intensity modulator designed for 1310 nm lasers. We use an

Fabry-Perot steady laser. The optical fiber transfers the pulses to the PD at 4 K. The fiber is attached via a glass tube guide to the PD mounted by a flip-chip process to a customized Si-carrier chip. This carrier chip was designed to provide bias lines and CPW for transfer of the electrical pulses. Those carrier chips were fabricated at PTB using Nb for the DC/HF lines and AuPd for the alignment markers and contact pads (PD and wire bond pads). An additional SiO_2 layer is deposited by PECVD to effectively protect the sensitive on-chip DC block capacitors against electrical damage during handling and operation. A significant advantage for practical use is that the optical fiber, which is connected via the glass tube, is removable. This tube is precisely aligned on-chip to the PD to ensure high efficiency of the illumination. Because the PD has a relatively large lens diameter of $100\text{ }\mu\text{m}$, it is easy to implement it in the setup to achieve robust and reliable operation. The flip-chip process of the PD is carried out at USN/JV in cooperation with NPL and PTB by using Au stud bumps and thermo-compression. The Si-carrier chip is glued and Al wire-bonded to a PCB. The JAWS-chip PCB and PD-chip PCB are arranged close together (4 cm) and are connected via a K-type edge launcher. Detailed optimizations and investigations of high-speed performance at room temperature and at 4 K were performed (Bardalen et al., 2017; Bardalen et al., 2018); the optical pulse setup is described in (Karlsen et al., 2019). Fig. 14 shows two PDs mounted on a Si-carrier chip made for the unipolar pulse drive of two JAWS arrays (left), a next-generation Si-carrier chip made for a bipolar pulse-drive of one JAWS array, with two PDs and two glass tubes mounted (center), and a glass tube with the removable optical fiber attached (right).

Using a one-channel optical pulse drive, unipolar sine waveforms were synthesized with stable operation margins using a JAWS array of 3000 junctions in a signal frequency range from 60 Hz up to 10 kHz. Clock frequencies up to 15 GHz, which corresponded to the maximum speed of the PPG and the PD, were used to generate output voltages of 6.6 mV RMS resp. 18.6 mV PP with a $\Sigma\Delta$ code amplitude of 0.2 (Kieler et al., 2019). Fig. 15 shows the frequency spectrum and time domain of a sine waveform synthesized at 12 GHz with a $\Sigma\Delta$ code amplitude of 0.2 and a $\Sigma\Delta$ code length of 8 Mbit. This waveform has a signal frequency of 1500 Hz and signal amplitude of 5.26 mV RMS resp. 14.9 mV PP. The signal-to-noise ratio is 90 dBc and the laser-bias operation margins are 1 mA. The time domain clearly shows the DC shift of the waveform generated due to the unipolar pulse-drive with only one PD.

Fig. 14 Photographs of two PDs mounted on a Si-carrier chip (left), a different Si-carrier chip with two PDs and two glass tubes mounted (center), and a glass tube with a removable optical fiber attached (right).

Fig. 15 Frequency spectrum and time domain of a unipolar sine waveform generated with the one-channel optical pulse drive.

Therefore, only one Shapiro step is used, and the output voltage is reduced by 50%. A two-channel optical pulse-drive setup for generating bipolar waveforms is under development at PTB. The first spectrally pure bipolar waveforms were synthesized with a signal amplitude of 12.5 mV RMS resp. 35.4 mV PP at a signal frequency of 10 kHz (Herick et al., 2020).

Another approach to increasing the output voltage of JAWS by parallel operation of several JAWS arrays is to use an on-chip power divider. This approach was successfully implemented by using Wilkinson power dividers for JAWS at NIST (USA) (Flower-Jacobs et al., 2016) and by using CPW-CPS dividers for the programmable voltage standard of AIST (Japan) (Yamamori and Kohjiro, 2016). At PTB, modified versions of both types of dividers were integrated into our JAWS circuits (Tian et al., 2020; Tian et al., 2021; Tian, 2022). Different versions of these dividers were developed to optimize the insertion and return loss and achieve an optimal amplitude balance. Fig. 16 shows an example of the layout (left) and the realized chip (right) of a one-stage three-section Wilkinson divider, wherein two dividers were integrated onto a 10 mm × 15 mm chip. The one-stage divider splits the HF chain into two chains to supply two independent JAWS arrays. Because Wilkinson dividers are known to have a small bandwidth, a three-section divider was integrated. Each section had a different center frequency. Here, the intention was to enlarge the overall bandwidth of this divider and consequently improve the performance of the pulse-mode operation.

The IVC of both arrays of a one-stage Wilkinson divider is shown in Fig. 17. The circuit contains $N = 9000$ per array with 3-stacked junctions, i.e., 18,000 junctions in total. Basic Josephson junction parameters can be derived from this: critical current $I_c = 3.3$ mA, normal resistance $R_n = 3$ m Ω . Thus, the following parameters can be calculated: the critical current density $j_c = 5.5$ kA/cm² (junction area $A = 59.84$ μm^2), the characteristic voltage $V_c = 10.3$ μV and the characteristic frequency $f_c = 5.0$ GHz. Both IVCs agree very well and an I_c -spread of about 5% was estimated from these IVCs.

To evaluate the large bandwidth of these dividers, the IVC was measured for different pulse repetition frequencies in the range from 3 GHz to 15 GHz for one array (Fig. 18). For each IVC, the pulse amplitude was adjusted to $0.7 \times I_c$. For the sake of clarity, the IVCs were derived and plotted using a color-coding scheme: the white area shows the Shapiro steps, while the multicolored areas are the non-quantized parts of the IVC between those steps. First, the $\pm$ first Shapiro steps (SS) are created over the whole frequency

Fig. 16 Layout (left) and photograph (right) of a JAWS chip with two arrays with a one-stage three-section Wilkinson divider.

Fig. 17 Current-voltage characteristic of both arrays of a one-stage Wilkinson divider containing 9000 junctions per array.

Fig. 18 Derivation of current-voltage characteristic vs. pulse repetition frequency for one array of a one-stage Wilkinson divider (9000 junctions).

Fig. 19 Frequency spectrum and time domain of a sine waveform generated with the one-section Wilkinson divider.

range with a minimum step width of about 0.8 mA. Second, the Shapiro step generation is (as expected) fairly symmetrical for positive and negative pulses. Both features are the precondition of the synthesis of spectrally pure waveforms in pulse-mode operation.

Below, Fig. 19 illustrates the time and frequency domain of a sine waveform synthesized with both arrays of this Wilkinson divider, which has 18,000 junctions in total. At a clock frequency of $f_{\text{clock}} = 14$ GHz and a $\Sigma\Delta$ code amplitude of $A_{\Sigma\Delta} = 0.814$, it was possible to synthesize a waveform at $f_{\text{signal}} = 100$ Hz and $V_{\text{signal}} = 300$ mV_{RMS} (848 mV_{PP}), providing small but stable operation margins of 180 μ A. An excellent signal-to-noise ratio of 130 dBc was achieved.

Applications

The outstanding features of JAWS have already allowed several applications in AC voltage metrology to be demonstrated at PTB. Several international research projects funded in large part by the European Union have helped establish a strong and fruitful collaboration between several national metrology institutes. The following projects were funded from 2001 until 2019: “JAWS” (EU project, 2001), “JoSy” (EU project, 2007), “Q-Wave” (EU project, 2013), “ACQ-Pro” (EU project, 2015), “Dig-AC” (EU project, 2018) and “QuADC” (EU project, 2016). In this way, we were able to extensively explore the limitations of JAWS in the field of voltage metrology, and to set new milestones in the quality of high-precision measurements. The features of the JAWS investigated included the following (the NMI partners of PTB are denoted in parentheses):

1. AC-DC transfer measurements with a trans-conductance amplifier (NMIA [Australia])
2. Characterization of Keysight 3458A (SIQ [Slovenia], CEM [Spain])
3. AC-DC transfer (up to 1 MHz) with Fluke792A in a mini-cryostat (VSL [Netherlands])
4. Characterization of analog-to-digital converters (ADCs) (CMI [Czech Republic])
5. Systematic error analysis (Tübitak [Turkey])
6. Characterization of voltage dividers (SP [Sweden])
7. JAWS based μ V-synthesizer
8. JAWS in a cryocooler (INRIM [Italy])
9. Impedance/quadrature bridge (METAS [Switzerland])
10. JAWS Johnson-noise thermometry (JNT) (PTB Berlin)

Some of these activities will be described in the following section.

A novel method for the calibration of fast ADCs using JAWS with a sophisticated constructed waveform was suggested in (Sira et al., 2019). Here, the aim was to determine the gain and time stability of an ADC for different frequencies and amplitudes almost simultaneously, or even in a single measurement if possible. By reordering the sampled data and the numerous steps involved in the data processing, other basic properties of an ADC can also be estimated such as phase, integral nonlinearity (INL), differential nonlinearity (DNL), effective number of bits (ENOB), and signal-to-noise and distortion ratio (SINAD).

The waveform selected is shown in Fig. 20. It consists of 4 sections and 16 subsections, as clearly indicated in the time domain of the signal. The frequency of the sine wave is different for each of the four sections. Each subsection contains four different signal amplitudes, and each amplitude repeats 10 periods of this single-tone sine wave to evaluate the time stability. Frequencies, amplitudes, and periods define the total number of 160 calibration points of this signal. By continuously repeating this waveform, more statistical data can be derived.

We selected a National Instruments PXI 5922 as the device under test (DUT). The PXI 5922 is used in many calibration laboratories because of its flexibility. Its maximum sampling frequency is 15 MSa/s. Because the device has internal $\Sigma\Delta$ modulation

Fig. 20 Frequency spectrum and time domain of a complex multitone sine waveform for calibration of an ADC.

electronics, the resolution increases with decreasing sampling frequency. For sampling frequencies below 500 kSa/s, the resolution is nominally 24 bit. Two full-scale ranges, 2 and 10 V, are available. Because of the small maximum output voltage of the JAWS, only the lower range of the digitizer was used. The waveform was constructed to accommodate some restrictions of the devices used – for example, limited values for the sampling rate of the PXI or the minimum bit resolution of 128 bit for the PPG. These restrictions explain the special values of the PPG clock frequency and code length.

The main waveform properties and settings of the PPG and PXI5922 were the following:

1. Number of junctions $N = 54,000$ (six arrays in series)
2. PPG clock frequency $f_{\text{clock}} = 13.762\ 56\ \text{GHz}$
3. PPG code length $L_{\Sigma\Delta} = 215,040,000$
4. PPG code amplitude $A_{\Sigma\Delta} = 0.06/0.18/0.30/0.42$
($A_{\text{main-}\Sigma\Delta} = 0.6 \times \text{pre-factors } A_F = 0.1/0.3/0.5/0.7$)
5. PPG code repetition rate: 32
6. PXI sampling rate: 480 kSa/s
7. Signal frequencies $f_{\text{signal}} = 150/300/600\ \text{Hz}/1200\ \text{Hz}$
8. Signal amplitudes $V_{\text{signal}} \approx 0.18/0.55/0.92/1.3\ \text{V PP}$

The main output of the calibration (gain errors) can be obtained at different amplitudes and frequencies. By repeating the waveform, the gain stability can also be measured. The advantage of this method is that all gains are measured in a very short period of time. Thus, the stability is measured at multiple calibration points simultaneously.

Another application is the characterization of a sampling AC voltmeter. The aim of this approach was to evaluate the noise performance of such a device in sampling mode as a function of different device settings, e.g., aperture time.

For this application, a special waveform was again synthesized using the JAWS: a band-limited square waveform (BLSW), which was suggested in (Lapuh et al., 2017) (Fig. 21). This waveform corresponds to a square wave at 52 Hz, where only a certain number of higher harmonics of the frequency spectrum are generated and all other higher harmonics above 20 kHz are cancelled by the signal.

As the DUT, we selected an Keysight 3458A digital multimeter, as it provided high accuracy for sampling low-frequency signals and it is widely used in NMIs and calibration laboratories. Detailed knowledge of the noise performance (among other things) is a precondition for high-accuracy measurements with low uncertainties.

The main waveform properties and settings of the PPG and PXI5922 were the following:

1. Number of junctions $N = 24,000$ (two arrays in series)
2. PPG clock frequency $f_{\text{clock}} = 13\ \text{GHz}$
3. PPG code length $L_{\Sigma\Delta} = 250,000,000$

Fig. 21 Frequency spectrum and time domain of a band-limited square waveform for calibration of an AC voltmeter.

4. PPG code amplitude $A_{\Sigma\Delta} = 0.32$
5. PPG code repetition rate: 1
6. JAWS bias current operation margins: 0.5 mA
7. Signal frequencies $f_{\text{signal}} = 52$ Hz
8. Signal amplitude $V_{\text{signal}} = 150$ mV RMS
9. Number of higher harmonics: 192
10. Only odd harmonics are synthesized: 1, 3, 5, ..., 383

“Simple” sine waveforms at different frequencies and amplitudes are also suitable for this application, as demonstrated in (de Aguiar et al., 2019).

Another application of JAWS is to use it as a precision microvolt synthesizer for the generation of small DC or AC signals (Behr et al., 2017). These signals can be used, for instance, to calibrate nanovoltmeters (DC) or lock-in amplifiers (AC). The JAWS is capable of generating DC/AC signals in the nanovolt range easily if the pulse repetition frequency chosen for the operation of the chip is far below the characteristic voltage of the Josephson junction. In contrast to continuous wave operation, broad Shapiro steps will be generated in this pulse-mode operation regime too (Benz and Hamilton, 1996). We demonstrated this for the first time experimentally for this application.

In order to generate DC voltages by means of the JAWS, two methods can be applied. In the first, more obvious method, simple pulse codes with a constant pulse repetition frequency will be generated. By choosing the pulse code length and the clock frequency, the desired signal voltage can be tuned. The more advanced method invokes higher-order $\Sigma\Delta$ modulation. Here, the pulse repetition frequency in the pulse code is not constant. The advantage of this method is that any desired output voltage can be adjusted easily and precisely by selecting the corresponding $\Sigma\Delta$ code amplitude and (if necessary) the clock frequency.

The typical signal voltage range for the calibration of a nanovoltmeter is about $V = 10$ nV to $V = 100$ μ V. For this calibration, we used a JAWS array with $N = 9000$ junctions. For each DC signal voltage, a different $\Sigma\Delta$ code ($-1/0/+1$) with a constant length of $L_{\Sigma\Delta} = 128$ Mbit was calculated in advance. The clock frequency was also kept constant: $f_{\text{clock}} = 5$ GHz. To synthesize, for example, a DC voltage of 10 nV with these parameters, the resulting $\Sigma\Delta$ code amplitude is very small ($A_{\Sigma\Delta} \approx 1.5 \times 10^{-7}$) and only $1.1 \times 10^{-5}\%$ of the code contains “1”s. To synthesize a “zero” voltage, on the other hand, the $\Sigma\Delta$ code contains only “0”s. When this “zero” code is applied to the JAWS array, no flux quanta are transferred, and the Josephson junctions are kept in the superconducting state below the critical current, giving a “perfect” zero signal output as required for the calibration. The significant advantage of a perfect “zero” voltage being set by choosing the “zero” code automatically by means of a program is that no switches are needed (including those inside an instrument) to set the voltage to zero or to reverse its polarity.

Due to the small voltages, it was not necessary to apply a compensation signal (Benz et al., 2001), i.e., no additional DC bias currents were needed. The Shapiro steps can be centered around the zero bias current simply by tuning the positive or negative pulse amplitude adjusted at the PPG. A positive pulse amplitude is used to select the first positive Shapiro step and the negative pulse amplitude is adjusted for the first negative Shapiro step. Both pulse amplitudes of the PPG were constant for all pulse repetition frequencies in the $\Sigma\Delta$ code (and consequently for all DC voltages) to be generated. Therefore, the entire JAWS setup is comparatively simple. Additionally, this demonstrates that the Shapiro step width is fully independent of the pulse repetition frequency.

To avoid high thermal voltages in the setup, twisted-pair copper wires (in contrast to coaxial wires) were used to connect the array to the DUT (Magnicon NVM1, 10 mV-range), keeping the thermal voltages stable and below 500 nV. Stable and low thermal voltages are important for precise DC voltage measurements.

The minimum pulse repetition frequency applied was only 540 Hz, which is far below the characteristic frequency of $f_c = 7.6$ GHz, which produces a minimum synthesized voltage of only $V_{\text{JJ}} = 1.1$ pV per Josephson junction:

1. Minimum pulse repetition frequency: $f_p = 540 \text{ Hz} \approx 0.00000007 \cdot f_c$
2. Minimum voltage per single junction: $V = 1.1 \text{ pV} \approx 0.00000007 \cdot V_c$

The minimum possible voltage has not yet been explored, as it was possible to use the full available PPG memory of 512 MByte, tune down the clock frequency of the PPG, and also reduce the $\Sigma\Delta$ code amplitude. However, from a practical point of view, a minimum voltage of 10 nV is sufficiently small for a typical nanovoltmeter calibration.

The complete measurements were taken fully automatically, and we determined 24 voltage calibration points in 60 min, thus providing a low uncertainty. The results are shown in Fig. 22. The deviation from the linearity is plotted in a measurement range from -4 μ V to $+4$ μ V. The error bars indicate Type A uncertainties ($k = 1$). The measurements agree well with the conventional data achieved by means of a potentiometer method, which shows noticeably higher uncertainties.

By using a similar procedure, the generation of AC voltages is also possible for the calibration of AC devices that are sensitive to small input signals. In (Behr et al., 2017), a lock-in amplifier in the range from 80 Hz to 100 kHz in a signal voltage range from 1 μ V to 50 mV was also calibrated. The following features of this device were characterized:

1. Linearity
2. Gain vs. frequency
3. Gain vs. voltage range
4. AC gain selection
5. Harmonic content influence

and therefore reduces the measurement time compared to conventional ratio bridges using room-temperature resistance standards. This can be used to investigate graphene QHR samples and give important feedback on the manufacturing process. Within ratio measurements, the time-dependent drift of a 12.9 k resistance standard was determined in a substitutional measurement and agreed within the fit uncertainty of 0.23 n Ω / Ω with the measurements of a 14-bit cryogenic current comparator. This gives an initial impression of the high reproducibility and flexibility of the whole setup. The excellent features of the four-terminal-pair JAWS-based impedance bridge makes it an ideal tool for future metrological applications.

The PTB JAWS was recently used for the realization of the quantum-based electronic Kelvin. Johnson-noise thermometry (JNT) will enable the development of a primary thermometer up to 1000 K in the future (Kraus et al., 2018; Drung and Krause, 2021; Drung et al., 2022). The JAWS will be implemented in such a system to provide a pseudo-random quantum noise source such as the one suggested by NIST. These activities were prompted by the 2020 re-definition of the basis unit of the Kelvin by setting a fixed value for the Boltzmann constant; this re-definition has enabled the direct definition of the Kelvin in the whole temperature range via primary thermometry. This is important for future objectives in thermodynamical temperature measurements and future development of the international temperature scale. The work on the JAWS-based JNT is still in progress in a collaborative effort between different departments of PTB.

Conclusion

We have presented the basic principle of JAWS and demonstrated the capability of generating quantized high-precision and arbitrary waveforms in the time and frequency domain with extremely high spectral purity. A brief overview of the fabrication technology for highly integrated JAWS circuits with more than 50,000 junctions per chip has been given. We have also introduced stacked junction technology with up to 5-stacked junctions. New approaches designed to further increase the output voltage and to simplify the JAWS setup have been presented, including on-chip power dividers and optical pulse drives for the JAWS. Certain applications of the JAWS that have significant benefits for quantum AC voltage metrology have also been described. These new applications have resulted in numerous publications by PTB scientists in cooperation with our NMI partners over the last several years. For example, from 2018 to 2021, more than 30 papers were published, including conference papers. Within international research projects, PTB's JAWS chips have been distributed to NMIs in the Netherlands, the United Kingdom, Norway, Italy, Finland, Turkey, Russia, China and Argentina. The technology transfer between PTB and the Supracon company for commercialization purposes has also been initiated to make JAWS available to other NMIs, to calibration laboratories and to industry in the near future.

Abstract

In this chapter, I discuss the impact of concepts of Quantum Field Theory in modern Condensed matter physics. Although the interplay between these two areas is certainly not new, the impact and mutual cross-fertilization has certainly grown enormously with time, and Quantum Field Theory has become a central conceptual tool in condensed matter physics. In this chapter, I cover how these ideas and tools have influenced our understanding of phase transitions, both classical and quantum, as well as topological phases of matter, and dualities.

Key points

- Quantum Field Theory has a deep and wide impact on our understanding of modern condensed matter physics.
- The conceptual framework of the Renormalization Group and of the UV fixed point is the central concept in the theory and classical and quantum phase transitions.
- The renormalization group is the foundation for universality, scale, and conformal invariance at these fixed points.
- Here, I discuss quantum criticality in the 1D transverse field Ising model and in quantum antiferromagnets.
- Topology is also central to our understanding of condensed matter ranging from the role of vortices and magnetic monopoles to topological terms in effective actions.
- Duality and duality transformations and bosonization and fermionization transformations in condensed matter and gauge theories provide a nonperturbative framework to our understanding of these systems.
- Topology has provided a sharp definition of fractional charge, fractional statistics, braiding, and fusion of quasiparticles.
- Topological phases of matter are physical systems with long-range quantum entanglement characterized by topological invariants.

Introduction

Many (if not most) puzzling problems in condensed matter physics involve systems with a macroscopically large number of degrees of freedom often in regimes of large fluctuations, thermal and/or quantum mechanical. The description of the physics of systems of this type requires the framework provided by Quantum Field Theory. Although quantum field theory has its origins in high-energy physics, notably in the development of Quantum Electrodynamics, it has found a nurturing home in condensed matter physics.

There is a long history of cross-fertilization between both fields. Since the 1950s in many of the most significant developments in Condensed Matter Physics, Quantum Field Theory has played a key role if not in the original development but certainly in the eventual understanding the meaning and the further development of the discoveries. As a result, many of the discoveries and concepts developed in Condensed Matter have had a reciprocal impact in Quantum Field theory. One can already see this interplay in the development of the Bardeen–Cooper–Schrieffer theory of superconductivity (Schrieffer, 1964) and its implications in the theory of dynamical symmetry breaking in particle physics by Nambu (Nambu and Jona-Lasinio, 1961).

The close and vibrant relationship between both fields has continued to these days, and it is even stronger today than before. Many textbooks have been devoted to teaching these ideas and concepts to new generations of condensed matter physicists (and field theorists as well). The earlier texts focused on Green functions which are computed in perturbation theory using Feynman diagrams (Abrikosov et al., 1963; Fetter and Walecka, 1971; Doniach and Sondheimer, 1974), while the more modern ones have a broader scope, use path integrals and attack nonperturbative problems (Feynman and Hibbs, 1965; Feynman, 1972; Faddeev, 1976; Fradkin, 2013, 2021; Altland and Simons, 2010). In two recent books I have discussed many aspects of the interrelation between condensed matter physics and quantum field theory in more depth than I can do in this chapter (Fradkin, 2013, 2021).

Early years: Feynman diagrams and correlation functions

Quantum field theory played a key role in the development of the Theory of the Fermi Liquid (Pines and Nozières, 1966; Baym and Pethick, 1991). The theory of the Fermi liquid was first formulated by Landau using the framework of hydrodynamics and the quantum Boltzmann equation. Landau's ideas were later given a microscopic basis using Green functions and Feynman diagrams (Abrikosov et al., 1963), including the effects of quantum fluctuations at finite temperature and nonequilibrium behavior (Kadanoff and Baym, 1962; Kamenev, 2011). Linear response theory was developed, which allowed the computation of response functions (such as electrical conductivities and magnetic susceptibilities) from the computation of correlation functions for a given microscopic theory (Martin, 1968). In turn, correlation functions can be computed in terms of a set of Feynman diagrams. These concepts and tools borrowed many concepts from field theory including the study of the analytic structure of the generalized susceptibilities and the associated spectral functions (together with the use of dispersion relations). These developments led to the derivation of the fluctuation-dissipation theorem. These ideas were widely applied to metals (Baym and Pethick, 1991) and superconductors (Schrieffer, 1964), as well as to quantum magnets (Mattis, 1965).

The spectrum of an interacting system has low energy excitations characterized by a set of quantum numbers associated with the symmetries of the theory. These low energy excitations are known as *quasiparticles*. In the case of the Landau theory of the Fermi liquid (FL), the quasiparticle is a “dressed” electron: it is a low energy excitation with the same quantum numbers (charge and spin) and an electron but with a renormalized effective mass. There are many such quasiparticles in condensed matter physics. The correlation functions (the propagators) of a physical system have a specific analytic structure. In momentum (and frequency) space, the quasiparticle spectrum is given by the poles of the correlators.

The role of symmetries and, in particular of gauge invariance, in the structure of correlation functions was investigated extensively. A direct consequence of symmetries is the existence of Ward–Takahashi identities, which must be satisfied by all the correlation functions of the theory. Ward–Takahashi identities are exact relations that relate different correlation functions. Such identities contain a host of important results. For example, in a theory with a globally conserved charge, the Hamiltonian (and the action) have a global $U(1)$ symmetry associated with the transformation of the local field operator $\phi(x)$ (which can be fermionic or bosonic) to a new field $\phi'(x) = e^{i\theta}\phi(x)$ (where θ is a constant phase). Theories with a global continuous symmetry have a locally conserved current (and satisfy a continuity equation). The Ward–Takahashi identity requires the correlators of these currents (and densities) to be transverse (i.e., they should have vanishing divergence). In the absence of so-called quantum anomalies (which we will discuss below), global symmetries can be made local and become gauge symmetries.

In many circumstances, a global symmetry can be spontaneously broken. If the global symmetry is continuous, then the Ward–Takahashi identities imply the existence of gapless excitations known as Goldstone bosons. For example in the case of a superfluid, which has a spontaneously broken $U(1)$ symmetry the Goldstone boson is the gapless phase mode. Instead, the Néel phase of a quantum antiferromagnet has two gapless Goldstone bosons, the magnons of the spontaneously broken $SO(3)$ global symmetry of this state of matter. Another example is the Ward–Takahashi identity of quantum electrodynamics (QED), which

relates the electron self-energy to the electron–photon vertex function, which also holds in nonrelativistic electron fluids. In addition, these identities implied the existence of sum rules that the spectral functions must satisfy. All of these results became part of the standard toolkit of condensed matter experimentalists in analyzing their data and for theorists to make predictions. Ward–Takahashi identities and sum rules also imply restrictions on the allowed approximations which are often needed to obtain predictions from a microscopic model.

Critical phenomena

Classical critical phenomena

The late 1960s and particularly 1970s brought about an intense back and forth between condensed matter physics and field theory in the context of the problem of classical critical phenomena and phase transitions. This was going to become a profound revolution on the description of macroscopic physical systems with large-scale fluctuations. The problem of continuous (“second order”) phase transitions has a long history going back to the work of Landau (Landau, 1937; Landau and Lifshitz, 1959) who introduced the concept of an *order parameter field*. This turned out to be a powerful concept of broad applicability in many physical systems sometimes quite different from each other at the microscopic level.

A simple example is that of a ferromagnet with uniaxial anisotropy in which the spins of the atoms in a crystal are strongly favored to be aligned (or antialigned) along certain directions of the crystal. The simplest microscopic model for this problem is the Ising model, a spin system in which the individual spins are allowed to take only two values, $\sigma = \pm 1$. The partition function of the Ising model (in any dimension) is

$$Z = \sum_{[\sigma]} \exp \left(-\frac{J}{T} \sum_{\langle r, r' \rangle} \sigma(r) \sigma(r') \right) \quad (1)$$

where J is the exchange coupling constant and T is the temperature (measured in energy units); here $[\sigma]$ denotes the sum over the 2^N spin configurations (for a lattice with N sites), and $\langle r, r' \rangle$ are nearest neighbor sites of the lattice. The order parameter of the Ising model is the local magnetization $\langle \sigma(r) \rangle$ which, in the case of a ferromagnet, is uniform. The partition function of the Ising model can be computed trivially in one dimension. The solution of the two-dimensional Ising model by Onsager constituted a tour-de-force in theoretical physics (Onsager, 1944). Its actual meaning remained obscure for some time. The work of Schultz et al. (1964) evinced a deep connection between Onsager’s solution and the problem of the spectrum of one-dimensional quantum spin chains (Lieb et al., 1961) [specifically the one-dimensional Ising model in a transverse field (Pfeuty, 1970)]. One important result was that the Ising model was in fact a theory of (free) fermions which, crudely speaking, represented the configurations of domain walls of the magnet. However, even this simple model cannot be solved exactly in general dimension, and approximate mean field theories of various sorts were devised over time to understand its physics.

Landau–Ginzburg theory

Landau’s approach assumed that close enough to a phase transition, the important spin configurations are those for which the local magnetization varies slowly on lattice scales. In this picture, the local magnetization, on long enough length scales, becomes an order parameter field that takes values on the real numbers, and can be positive or negative. Thus, the order parameter field is effectively the average of local magnetizations on some scale large compared to the lattice scale, which we will denote by a real field $\phi(x)$. The thermodynamics properties of a system of this type in d dimensions can be described in terms of a free energy

$$F[\phi] = \int d^d x \left[\frac{\kappa}{2} (\nabla \phi(x))^2 + a(T - T_c) \phi^2(x) + u \phi^4(x) + \dots \right] \quad (2)$$

which is known as the Ginzburg–Landau free energy. Here, κ is the stiffness of the order parameter field; T_c is the (mean-field) critical temperature; and a and u are two (positive) constants. This expression makes sense if the transition is continuous and hence that the order parameter is small near the transition. The energy of the Ising model is invariant under the global symmetry $[\sigma] \mapsto [-\sigma]$. This is the symmetry of the group $\mathbb{Z}_2$. Likewise, the Ginzburg–Landau free energy has the global (discrete) symmetry $[\phi(x)] \mapsto [-\phi(x)]$ and also has a $\mathbb{Z}_2$ global symmetry.

In Landau’s approach, which was a mean field theory, the equilibrium state is the global minimum of this free energy. The nature of the equilibrium state depends on whether $T > T_c$ or $T < T_c$: for $T > T_c$ the global minimum is the trivial configuration, $\phi(x) = 0$ (this is the paramagnetic state), whereas for $T < T_c$, the equilibrium state is two fold degenerate, $\phi(x) = \pm (a(T_c - T)/2)^\beta$, with the two degenerate states being related by the $\mathbb{Z}_2$ symmetry (this is the ferromagnetic state). In the Landau theory, the critical exponent of the magnetization is $\beta = 1/2$ and the critical exponent of the correlation length is $\nu = 1/2$. However, in the case of the 2D Ising model, the order parameter exponent is $\beta = 1/8$ (Yang, 1952) and the correlation length exponent is $\nu = 1$. These (and other) apparent discrepancies led many theorists for much of the 1960s believe that each model was different and that these behaviors reflected microscopic differences. In addition, Landau’s theory was regarded as phenomenological and believed to be of questionable validity.

The renormalization group

This situation was to change with the development of the Renormalization Group, due primarily to the work of Kadanoff (Kadanoff, 1966a, b; Efrati et al., 2014) and Wilson (Wilson, 1971a, b; Wilson and Fisher, 1972; Wilson and Kogut, 1974; Wilson, 1975, 1983). The renormalization group was going to have (and still has) a profound effect both in condensed matter physics and in Quantum Field Theory (and beyond).

Scaling

Several phenomenological theories were proposed in the 1960s to describe the singular behavior of physical observables near a continuous phase transition (Patashinskii and Pokrovskii, 1966; Fisher, 1967, 1974). These early works argued that in order to explain the singular behavior of the observables, the free energy density had to have a singular part which should be a homogeneous function of the temperature, magnetic field, etc. A function $f(x)$ is homogeneous if it satisfies the property that it transforms irreducibly under dilations, that is, $f(\lambda x) = \lambda^k f(x)$, where λ is a real positive number (a scale) and k is called the degree. These heuristic ideas then implied that the critical exponents should obey several identities. In 1966, Kadanoff wrote an insightful paper in which he showed that the homogeneity hypothesis implied that in that regime these systems should obey scaling. He showed that this can be justified by performing a sequence of block-spin transformations in which the configurations that vary rapidly at the lattice scale a become averaged at the scale of a larger sized block of length scale $ba > a$, which resulted in a renormalization of the coupling constants from $\{K\}$ at scale a to $\{K'\}$ at the new scale ba (Kadanoff, 1966a; Efrati et al., 2014). In other words, the block spin transformation amounts to a scale transformation and a renormalization of the couplings (and operators). From this condensed matter/statistical physics perspective, the important physics is in the long-distance (“infrared”) behavior.

A significant consequence of these ideas was that close enough to a critical point, if the distance $|x - y|$ between two local observables $O(x)$ and $O(y)$ is large compared to the lattice spacing a but small compared to the correlation length ξ , their correlation function takes the form of a power law

$$\langle O(x)O(y) \rangle \sim \frac{\text{const.}}{|x - y|^{2\Delta_O}} \quad (3)$$

where Δ_O is a positive real number known as the scaling dimension of the operator O (Patashinskii and Pokrovskii, 1966; Kadanoff, 1966a; Kadanoff et al., 1967). These conjectures were known to be satisfied in the nontrivial case of the 2D Ising model (Kadanoff, 1966b), as well as in the Landau–Ginzburg theory once the effects of Gaussian fluctuations were included (Kadanoff et al., 1967). For example, in the 2D Ising model, the scaling dimension of the local magnetization σ is $\Delta_\sigma = 1/8$ and of the energy density ε is $\Delta_\varepsilon = 1$, which were sufficient to explain all the singular behaviors known at that time.

The concept of renormalization actually originated earlier in quantum field theory as part of the development of QED. In QED, the notion of renormalization was used to “hide” the short distance (“ultraviolet”) divergencies of the Feynman diagrams needed to compute physical processes involving electrons (and positrons) and photons, that is, their strong, divergent, dependence of an artificially introduced short-distance cutoff or regulator. In particular, the sum of the leading diagrams that enter in the electron–photon vertex amounted to a redefinition (renormalization) of the coupling constant. It was observed by Murray Gell-Mann and Francis Low that this renormalization was equivalent to the solution of a first-order differential equation that governed the infinitesimal change of the coupling, the fine structure constant $\alpha = e^2/4\pi$, under an infinitesimal change of the UV cutoff Λ (Gell-Mann and Low, 1954)

$$\Lambda \frac{d\alpha}{d\Lambda} \equiv \beta(\alpha) = \frac{2}{3\pi} \alpha^2 + O(\alpha^3) \quad (4)$$

where $\beta(\alpha)$ is the Gell-Mann–Low beta function. Except for the work by Bogoliubov and Shirkov (1959), this reinterpretation by Gell-Mann and Low was not actively pursued, partly because it predicted that the renormalized coupling became very large at short distances, $\alpha \rightarrow \infty$, and, conversely, it vanished in the deep long-distance regime, $\alpha \rightarrow 0$ (if the electron bare mass is zero). In other words, QED is strongly coupled in the UV and trivial in the IR. The same behavior was found in the case of the theory of a scalar field $\phi(x)$ with an ϕ^4 interaction, which is relevant in the theory of phase transitions. In addition to these puzzles, the 1960s saw the experimental development of the physics of hadrons which involve strong interactions. For these reasons, for much of that decade most high-energy theorists had largely abandoned the use of quantum field theory, and explored other, phenomenologically motivated, approaches (which led to an early version of string theory.) At any rate the notion that the physics may depend on the scale was present as was the notion that in some regimes field theories may exhibit scale invariance at least in an approximate form.

The operator product expansion

The next stage of the development of these ideas was the concept of the operator product expansion (OPE). If we denote by $\{O_i(x)\}$ the set of all possible local operators in a theory (a field theory or a statistical mechanical system near criticality), then the product of two observables on this list closer to each other than to any other observable (and to the correlation length ξ) obeys the expansion

$$\lim_{x \rightarrow y} O_j(x)O_k(y) = \lim_{x \rightarrow y} \sum_l \frac{C_{jkl}}{|x - y|^{\Delta_l + \Delta_k - \Delta_j}} O_l\left(\frac{x + y}{2}\right) \quad (5)$$

where this equation should be understood as a weak identity, valid inside an expectation value. Remarkably, this concept was derived independently and simultaneously by Kadanoff (1969) (who was working in critical phenomena), by Wilson (1969)

(who was interested in the short distance singularities arising in Feynman diagrams), and by Polyakov (1970, 1974) (also working in critical phenomena). In Eq. (5), $\{\Delta_j\}$ are the scaling dimensions of the operators $\{O_j\}$. The coefficients C_{jkl} are (like the dimensions) universal numbers. In a follow-up paper, Polyakov showed that if the theory has conformal invariance, that is, scale invariance augmented by conformal transformations which preserve angles, then, provided the operators O_j are suitably normalized, the coefficients C_{jkl} of the OPE are determined by a three-point correlator

$$\langle O_j(x) O_k(y) O_l(z) \rangle = \frac{C_{jkl}}{|x-y|^{\Delta_j} |y-z|^{\Delta_k} |z-x|^{\Delta_l}} \quad (6)$$

where $\Delta_{jk} = \Delta_j + \Delta_k - \Delta_l$. These results constitute the beginnings of conformal field theory (CFT). In a nontrivial check, Kadanoff and Ceva showed that the OPE holds for the local observables of the 2D Ising model (Kadanoff and Ceva, 1971).

Fixed points

The next and crucial step in the development of the Renormalization Group was made by Wilson. Wilson was a high-energy theorist who wanted to know how to properly define a quantum field theory and the physical meaning of renormalization.

In a Lorentz invariant quantum field theory, one is interested in the computation of the expectation value of time-ordered operators. In the case of a self-interacting scalar field $\phi(x)$ in D -dimensional Euclidean space-time, obtained by analytic continuation from Minkowski spacetime to imaginary time, the observables are computed from the functional (or path) integral by functional differentiation of the partition function

$$Z = \int \mathcal{D}\phi \exp \left(-S(\phi, \partial_\mu \phi) + \int d^D x J(x) \phi(x) \right) \quad (7)$$

with respect to the local sources $J(x)$. For a scalar field, the Euclidean action is

$$S = \int d^D x \left[\frac{1}{2} (\partial_\mu \phi(x))^2 + \frac{m^2}{2} \phi^2(x) + \frac{\lambda}{4!} \phi^4(x) \right] \quad (8)$$

which has the same form as the free energy of the Landau–Ginzburg theory of phase transitions shown in Eq. (2). It is apparent that the Landau–Ginzburg theory is the classical limit of the theory of the scalar field whose partition function is a sum over all histories of the field. It is easy to see that an expansion of the partition function (or of a correlator) in powers of the coupling constant λ can be cast in the form of a sum of Feynman diagrams. To lowest order in λ a typical Feynman diagram involves a one-loop integral in momentum space of the form

$$I(p) = \int \frac{d^D q}{(2\pi)^D} \frac{1}{(q^2 + m^2)((q-p)^2 + m^2)} \quad (9)$$

As noted by Wilson in his Nobel Lecture (Wilson, 1983), this integral has large contributions from the IR region of small momenta $q \sim 0$, but for any dimension $D \geq 4$ has a much larger contribution from large the UV region of large momenta, which requires the introduction of a UV cutoff Λ in momentum space (or a lattice spacing a in real space by defining the theory on a hypercubic lattice). In quantum field theory, one then has to require that somehow one takes the limit $a \rightarrow 0$ (or $\Lambda \rightarrow \infty$). To take this limit in the field theory is very much analogous to the definition of a conventional integral in terms of a limit of a Riemann sum. The difference is that this is a *functional* integral. While for a function of bounded variation in a finite interval (a, b) , the limit of a partition of the interval into N steps each of length Δx such that $N\Delta x = b - a$ exists and defines the integral of the function

$$\lim_{\Delta x \rightarrow 0} \lim_{N \rightarrow \infty} \sum_{j=1}^N f(x_j) \Delta x_j = \int_a^b dx f(x), \quad (10)$$

the analogous statement does not obviously exist in general for a *functional integral*, that is, an integral over a space of functions, which is what is required. In fact, although thousands of integrals of a function are known to exist, there are extremely few examples for a functional integral. Moreover, in order to take the *continuum limit*, the lattice spacing must approach zero, $a \rightarrow 0$. This means that physical scales, such as the correlation length ξ , must diverge in lattice units so that they can be fixed in physical units. But to do that, one has to be asymptotically close to a continuous phase transition! Hence, the problem of defining a quantum field theory is *equivalent* to the problem of critical phenomena at a continuous phase transition!

Wilson gave a systematic formulation to the Renormalization Group by generalizing the earlier ideas introduced by Kadanoff and the earlier work by Gell-Mann and Low. Wilson's key contribution was the introduction of the concept of a *fixed point* of the Renormalization Group transformation (Wilson, 1971a, b; Wilson and Fisher, 1972; Wilson and Kogut, 1974). As we saw, the block-spin transformation is a procedure for coarse graining the degrees of freedom of a physical system resulting in a renormalization of the coupling constants. Upon the repeated action of the RG transformation, its effect can be pictured as a *flow* in the space of coupling constants. However, in addition to integrating short distance degrees of freedom, one needs to restore the units of length, which have changed under that process. This requires a rescaling of lengths. Once this is done, Wilson showed that the resulting RG flows necessarily have *fixed points*, special values of the couplings which are invariant (fixed) under the action of the RG

transformation. He then deduced that at a fixed point, the theory has no scales, aside from the linear size L of the system and the microscopic UV cutoff (the lattice spacing a in a spin system).

This analysis means that for length scales long compared to $a \rightarrow 0$ but short compared to $L \rightarrow \infty$ the theory acquired a new, emergent, symmetry: scale invariance. Therefore, at a fixed point, the correlators of all local observables must be homogeneous functions (hence, must scale).

Universality

A crucial consequence of the concept if the fixed point is that phase transitions can be classified into *universality classes*. Universality means that a large class of physical systems with different microscopic properties have fixed points with the same properties, that is, the same scaling dimensions, OPEs, and correlation functions at long distances independent on how they are defined microscopically. Although the renormalization group transformation is a transformation scheme that we define and, because of that the location in coupling constant space of the fixed point itself does depends on the scheme we choose, its universal properties are the same. Thus, universality classes depend only on features such as the space (and spacetime) dimension and the global symmetries of the system. But the systems themselves may be quite different. This we speak if the Ising universality class in 2D, on the superfluid (or XY) transition class in 3D, etc. This concept, which originated in the theory of phase transition, has been adopted and generalized in the development of CFT.

RG flows

Combined with the condition that the correlators decay at long separations, homogeneity implies that the correlators must have the form of Eq. (3). In addition, this equation also implies that at a fixed point the operators (the local observables) have certain scaling dimensions. Let us consider a theory close to a fixed point whose action we will denote by S^* . Let $\{O_j(x)\}$ be a complete set of local observables whose scaling dimensions are $\{\Delta_j\}$. The total action of the theory close to the fixed point then can be expanded as a linear combination of the operators with dimensionless coupling constants $\{g_j\}$

$$S = S^* + \int d^D x \sum_j g_j a^{\Delta_j - D} O_j(x) \quad (11)$$

Under a change of length scale $x \rightarrow x' = bx$, with $b > 1$, the operators (which must transform homogeneously) change as $O_j(bx) = b^{-\Delta_j} O_j(x)$. Since the phase space changes as $d^D x' = b^D d^D x$, we can keep the form of the action provided the coupling constants also change to compensate for these changes as $g'_j = b^{D-\Delta_j} g_j$. Let $b = |x'|/|x| = 1 + da/a$, where da is an infinitesimal change of the UV cutoff a . Then, if we integrate out the degrees of freedom in the range $a < |x| < a + da$, the rate of change of the coupling constants $\{g_j\}$ under this rescaling is

$$a \frac{dg_j}{da} \equiv \beta(g_j) = (D - \Delta_j)g_j + \dots \quad (12)$$

which we recognize as a Gell-Mann–Low beta function for each coupling constant.

This result says that if the scaling dimension $\Delta_j < D$, then the renormalized coupling will *increase* as we increase the length scale, $g'_j > g_j$, and along this direction in coupling constant space, the RG flows *away* from the fixed point. Conversely, if $\Delta_j > D$ the renormalized coupling flows to smaller values, $g'_j < g_j$ and the RG flows *into* the fixed point. We then say that an operator is *relevant* if its scaling dimension satisfies $\Delta_j < D$, and that it is *irrelevant* if $\Delta_j > D$. If $\Delta_j = D$, then we say that operator is *marginal*.

To go beyond this simple dimensional analysis, one has to include the effects of fluctuations. To lowest orders in the couplings one finds (Cardy, 1996)

$$a \frac{dg_j}{da} = (D - \Delta_j)g_j + \sum_{k,l} C_{jkl} g_k g_l + \dots \quad (13)$$

where $\{C_{jkl}\}$ are the coefficients of the OPE shown in Eq. (6). This expression is the general form of a perturbative renormalization group, and it is valid close enough to a fixed point.

Wilson and Fisher (1972) used a similar approach to analyze how fluctuations alter the results of the Landau–Ginzburg theory. They considered the partition function of Eq. (7) with the action of Eq. (8). Instead of working in real space, they considered the problem in momentum space and partitioned the field configurations into slow and fast modes

$$\phi(x) = \phi_{<}(x) + \phi_{>}(x) \quad (14)$$

where $\phi_{>}(x)$ are configurations whose Fourier components have momenta in the range $b\Lambda < |p| < \Lambda$, where Λ is a UV momentum cutoff and $b < 1$. Hence, if we choose $b \rightarrow 1$, the fast modes $\phi_{>}(x)$ have components in a thin momentum shell near the UV cutoff Λ . Conversely, the slow modes $\phi_{<}(x)$ have momenta in the range $0 \leq |p| < b\Lambda$. One can then use Feynman diagrams to integrate out the fast modes and derive an effective low-energy action with renormalized couplings. In the case of a free field theory (with $\lambda = 0$), the scaling dimension of the ϕ^4 operator is $\Delta_4 = 2(D - 2)$ whereas the ϕ^2 operator has dimension $\Delta_2 = D - 2$. Upon defining a dimensionless mass and coupling constant by $m^2 = t\Lambda^2$ and $\lambda = g\Lambda^{4-D}$, the beta functions are found to be (Fradkin, 2021)

$$\beta(t) = -\Lambda \frac{dt}{d\Lambda} = 2t + \frac{g}{2} - \frac{gt}{2} + \dots \quad (15)$$

$$\beta(g) = -\Lambda \frac{dg}{d\Lambda} = (4-D)g - \frac{3}{2}g^2 + \dots \quad (16)$$

(where we absorbed an uninteresting factor in the definition of the coupling constant).

The RG flows of Eq. (16) show that the free-field (Gaussian) fixed point at $g = 0$ is stable for $D > 4$ and the asymptotic IR behavior is the same as predicted by the Landau–Ginzburg theory. However, for $D < 4$, the free-field fixed point becomes unstable and a new fixed point arises at $g^* = \frac{2}{3}\epsilon + O(\epsilon^2)$, where we have set $\epsilon = 4 - D$. This is the Wilson–Fisher fixed point. At this fixed point, the correlation length diverges with an exponent $\nu = \frac{1}{2} + \frac{\epsilon}{12} + O(\epsilon^2)$, which deviates from the predictions of the Landau–Ginzburg theory. The small parameter of this expansion is ϵ , and this is known as the ϵ expansion.

The Wilson–Fisher (WF) fixed point is an example of a nontrivial fixed point at which the correlation length is divergent. It has only one relevant operator, the mass term, which in the IR flows into the symmetric phase for $t > 0$ and flows to the broken symmetry for $t < 0$. Conversely, in the UV, it flows into the WF fixed point. For these reasons, condensed matter physicists say that this is an IR unstable (or critical) fixed point while high-energy physicists say that it is the UV fixed point. At this fixed point, a nontrivial field theory can be defined with nontrivial interactions. UV fixed points also define examples of what in high-energy physics are called renormalizable field theories and can be used to define a continuum field theory.

The $D = 4$ -dimensional theory is special in that the ϕ^4 operator is marginal. As can be seen in Eq. (16), at $D = 4$ the beta function for the dimensionless coupling constant g does not have a linear term and is quadratic in g . In this case the operator is marginally irrelevant, and its beta function has the same behavior as the beta function of Gell-Mann and Low for QED. Such theories are said to have a “triviality problem” since, up to logarithmic corrections to scaling, there are no interactions in the IR and, conversely, become large in the UV.

There are also fixed points at which the correlation length $\xi \rightarrow 0$. These fixed points are IR stable (and in a sense trivial). These stable fixed points are sinks of the IR RG flows. Such fixed points define stable phases of matter, for example the broken symmetry state, and the symmetric (or unbroken state). However in the UV, they are unstable and in high-energy physics such fixed points correspond to nonrenormalizable field theories.

More sophisticated methods are needed to go beyond the lowest order beta functions of Eq. (13), and the computation of critical exponents beyond the leading nontrivial order. Possibly, the record high-precision calculations have been done for ϕ^4 theory for which the beta function is known to be $O(\epsilon^5)$. This has been achieved using the method of dimensional regularization (‘t Hooft and Veltman, 1972; Bollini and Giambiagi, 1972; Amit, 1980) (with minimal subtraction). Special resummation methods (Borel-Padé) have been used to do these calculations in $D = 3$ dimensions (Zinn-Justin, 2002). Remarkably, these results are so precise that in the case of the superfluid transition, which is well described by a ϕ^4 theory with a complex field, the results could only be tested in the microgravity environment of the International Space Station!

Asymptotic freedom

There are several physical systems of great interest whose beta function has the form

$$\beta(g) = Ag^2 + \dots \quad (17)$$

The coupling constant has a different interpretation in each theory and the constant $A > 0$, opposite to the sign of the beta function found in QED and ϕ^4 theory in $D = 4$ dimensions. This beta function means that while the associated operator is marginal, with this sign, it is actually marginally relevant. This also means that the fixed point is unstable in the IR but the departure from the fixed point is logarithmically small. Conversely, in the UV, the RG flows into the fixed point and the effective constant is weak at short distances. This is the origin of the term asymptotic freedom (Gross and Wilczek, 1973). The paradigmatic examples of theories with a beta function of this form are the Kondo problem, the 2D nonlinear sigma model, and the $D = 4$ dimensional Yang–Mills non-Abelian gauge theory.

The Kondo problem is the theory of a localized spin-1/2 degree of freedom in a metal. The electrons of the metal couple to this quantum impurity through an exchange interaction of the impurity and the magnetic moment density of the mobile electrons in the metal with coupling constant J . This problem is actually one-dimensional since only the s wave channel of the mobile (conduction band) electrons actually couple to the localized impurity. In 1970, Philip Anderson developed a theory of the Kondo problem in terms of the renormalization of the Kondo coupling constant g as a function of the energy scale (Anderson, 1970). Anderson used perturbation theory in J to progressively integrate the modes of the conduction electrons close to an effective bandwidth E_c and found that the beta function has the form of Eq. (17)

$$E_c \frac{dJ}{dE_c} = -\rho J^2 + \dots \quad (18)$$

where ρ is the density of states at the Fermi energy of the conduction electrons. This work implied that the free-impurity fixed point is IR unstable and that the effective coupling constant J increases as the energy cutoff E_c is lowered. He argued that at some energy scale, the Kondo scale, perturbation theory breaks down and that there is a crossover to a strong coupling regime, which is not accessible in perturbation theory.

Shortly thereafter, in 1973, Wilson developed a numerical renormalization group approach, which showed that the Kondo problem is indeed a crossover from the free impurity fixed point to the “renormalized” FL (Wilson, 1975). In addition, Wilson used the numerical renormalization group to examine the approach to the strong coupling fixed point and showed that it is characterized by a Wilson ratio, a universal number obtained from the low temperature specific heat and the impurity magnetic susceptibility (in suitable units). Wilson’s numerical RG predicted a number close to 2π for this ratio. In 1980, N. Andrei and P. Wiegmann showed (independently) that the Kondo problem is an example of an integrable field theory that can be solved by the Bethe ansatz (Andrei, 1980; Wiegmann, 1980). Their exact result was consistent with Wilson’s RG, including the numerical value of the Wilson ratio.

In 1972, Gerard ‘t Hooft and Martinus Veltman showed that Yang–Mills gauge theory is renormalizable (‘t Hooft and Veltman, 1972). This groundbreaking result opened the door to use quantum field theory to develop the theory of strong interactions in particle physics known as Quantum Chromodynamics (QCD). In 1973, Gross and Wilczek (1973) and, independently, Politzer (1973) computed the renormalization group beta function of Yang–Mills theory with gauge group G and found it to be of the same form as Eq. (17),

$$\Lambda \frac{dg}{d\Lambda} = -\frac{g^3}{16\pi^2} \frac{11}{3} C_2(G) + \dots \quad (19)$$

where g is the Yang–Mills coupling constant and Λ is a UV momentum scale. Here, $C_2(G)$ is the quadratic Casimir for a gauge group G . For $SU(3)$, the case of physical interest, $C_2(SU(3)) = 3$. This result implies that under the RG at large momenta (short distances), the Yang–Mills coupling constant flows to zero (up to logarithmic corrections). This result holds in the presence of quarks, provided the number of quark flavors is less than a critical value. Hence at short distances, the effective coupling is weak. Gross and Wilczek called this phenomenon asymptotic freedom. This behavior was consistent with the observation of weakly coupled quarks in deep inelastic scattering experiments. However, the flip side of asymptotic freedom is that at low energies (long distances), the coupling constant grows without limit, which implies that at low energies perturbation theory is not applicable. This strong infrared behavior suggested that in QCD quarks are permanently confined in color neutral bound states (hadrons). However, unlike the Kondo problem we just discussed, QCD is not an integrable theory (so far as we know) and to show that it confines has required the development of lattice gauge theory (Wilson, 1974; Kogut and Susskind, 1975). To this date, the best evidence for quark confinement has been obtained using large-scale Monte Carlo simulations in lattice gauge theory (Creutz et al., 1983).

We close this section with a discussion of an important case: the nonlinear sigma models. The $O(N)$ nonlinear sigma model is the continuum limit of the classical Heisenberg model for a spin with N components. Historically, the nonlinear sigma model is the effective field theory for pions in particle physics. We will discuss its role in the theory of quantum antiferromagnets in Section “Quantum antiferromagnets and nonlinear sigma models” and especially in the case of quantum antiferromagnetic spin chains in the Section “Nonlinear sigma models and antiferromagnetic quantum spin chains.”

The simplest nonlinear sigma model is a theory of an N -component scalar field $\mathbf{n}(x)$ which satisfies the unit length local constraint, $\mathbf{n}^2(x) = 1$. The Euclidean Lagrangian is

$$\mathcal{L} = \frac{1}{2g} (\partial_\mu \mathbf{n}(x))^2 \quad (20)$$

where g is the coupling constant (the temperature in the classical Heisenberg model). At the classical level, that is, in the broken symmetry phase, where $\langle \mathbf{n} \rangle \neq 0$, this model describes the $N - 1$ massless modes (Goldstone bosons) of the spontaneously broken $O(N)$ symmetry. Dimensional analysis shows that the coupling constant has units of ℓ^{D-2} . Hence, we expect to find marginal behavior at $D = 2$. In 1975, Alexander Polyakov used a momentum shell renormalization group in $D = 2$ dimensions and showed that the beta function of this model is (here a is the short-distance cutoff) (Polyakov, 1975b)

$$\beta(g) = a \frac{dg}{da} = \frac{N-2}{2\pi} g^2 + O(g^3) \quad (21)$$

Hence, in $D = 2$ dimensions also this theory is asymptotically free. As in the other examples we just discussed, asymptotic freedom here also implies that the coupling constant g grows to large values in the low-energy (long-distance) regime. In close analogy with Yang–Mills theory in $D = 4$ dimensions, Polyakov conjectured that the $O(N)$ nonlinear sigma model also undergoes dynamical dimensional transmutation (Gross and Wilczek, 1973), that the global $O(N)$ symmetry is restored and that for all values of the coupling constant g the theory is in a massive with a finite correlation length $\xi \sim \exp((N-2)/2\pi g)$. Extensive numerical simulations, used to construct a renormalization group using Monte Carlo simulations (Shenker and Tobochnik, 1980), showed that there is indeed a smooth crossover from the weak coupling (low temperature) regime to the high temperature regime where the correlation length is finite. The nonlinear sigma model is a renormalizable field theory in $D = 2$ dimensions (Brézin and Zinn-Justin, 1976). For $D > 2$ dimensions, it can be studied using the $2 + \epsilon$ expansion (Brézin and Zinn-Justin, 1976; Zinn-Justin, 2002), which predicts the existence of a nontrivial UV fixed point and a phase transition from a Goldstone phase to a symmetric phase.

It turns out that there is a significant number of asymptotically free nonlinear sigma models in $D = 2$ dimensions, many of physical interest (Friedan, 1985), in particular nonlinear sigma models whose target manifold is a coset space, a quotient of a group G and a subgroup H . The $O(N)$ nonlinear sigma model is an example since the broken symmetry space leaves the $O(N - 1)$ subgroup unbroken (the manifold of the Goldstone bosons). In that case, the quotient is $O(N)/O(N - 1)$, which is isomorphic to the $N - 1$ dimensional sphere S_{N-1} . In later sections, we will discuss other examples in which more general nonlinear sigma models play an important role.

Models on coset spaces arise in the theory of Anderson localization in $D = 2$ dimensions. Anderson localization is the problem of a fermion (an electron) in a disordered system in which the electron experiences a random electrostatic potential. In the limit of strong disorder Philip Anderson showed that all one-particle states are exponentially localized and the diffusion constant (and the conductivity) vanishes (Anderson, 1958). There was still the question of when it is possible for the electron to have a finite diffusion constant (and conductivity). In $D = 2$ dimensions, the conductivity is a dimensionless number which suggests that this may be the critical dimension for diffusion. Abrahams, Anderson, Licciardello, and Ramakrishnan used a weak disorder calculation to construct a scaling theory that implied that in $D = 2$ dimensions, the RG flow of the conductivity at long distances (large samples) flows to zero and all states are localized (Abrahams et al., 1979). Shortly thereafter, Wegner gave strong arguments that showed that the existence of diffusion implied that there are low-energy “diffusion” modes which behaved as Goldstone modes of a nonlinear sigma model on the quotient manifold $O(N_+ + N_-)/O(N_+) \times O(N_-)$ in the “replica limit” $N_{\pm} \rightarrow 0$ (Wegner, 1979). A field theory approach to this nonlinear sigma model was developed by McKane and Stone (1981) and by Hikami (1981).

Quantum criticality

Quantum criticality is the theory of a phase transition of a system (e.g., a magnetic system) at zero temperature that occurs as a coupling constant (or parameter) is varied continuously. Although not necessarily under that name, this question has existed as a conceptual problem for a long time. In particular, already in 1973, Wilson considered the problem of the behavior of quantum field theories below four spacetime dimensions and their phase transitions (Wilson, 1973).

The modern interest in condensed matter physics stems from discoveries made since the late 1980s. Since that time the behavior of condensed matter systems at a *quantum* critical point has emerged as a major focus in the field. There were several motivations for this problem. One was (and still is) to understand the behavior of quantum antiferromagnets in the presence of frustrating interactions. Frustrating interactions are interactions that favor incompatible types of antiferromagnetic orders. The result is the presence of intermediate nonmagnetic “valence bond” phases that favor the formation of spin singlets between nearby spins. These phases typically either break the point group symmetry of the lattice or are spin liquids (which will be discussed below). Another motivation is that doped quantum antiferromagnets typically harbor superconducting phases (among others) whose high-temperature behavior is a “strange” metal that violates the basic assumptions (and behaviors) of FLs. The most studied version of this problem is the case of the copper oxide high temperature superconductors. It was conjectured that there is a quantum critical point inside the superconducting phase at which the antiferromagnetic order (or other orders) disappears and which may be the reason for the strange metal behavior above the superconducting critical temperature. Many of these questions are discussed in depth by Sondhi et al. (1997) and in the textbook by Sachdev (2011).

Dynamic scaling

We will consider a general quantum phase transition and assume that it is scale invariant. However, except for the case of relativistic quantum field theories, in condensed matter systems, space and time do not need to scale in the same way. Let us assume that the system of interest has just one coupling constant g and that the system of interest has a quantum phase transition (at zero temperature) at some critical value g_c between two phases, for instance one with a spontaneously broken symmetry and a symmetric phase. If the quantum phase transition is continuous, then the correlation length ξ will diverge at g_c and so will the correlation time ξ_τ . However, these two scales are in general different and do not necessarily diverge at the same rate. So, in general, if some physical quantity is measured at the quantum critical point at some momentum $\mathbf{p}$ and frequency ω , the length scale of the measurement is $2\pi/|\mathbf{p}|$ and at a frequency is $\omega \sim |\mathbf{p}|^z$, where z is the dynamic critical exponent. Let us say that we measure the observable O at momentum $\mathbf{p}$ and frequency ω at g_c . Scale invariance in both space and time means that at g_c , the observable $O(\mathbf{p}, \omega)$ at momentum $\mathbf{p}$ and frequency ω must scale as

$$O(\mathbf{p}, \omega) = |\mathbf{p}|^{-\Delta_O} \tilde{O}(|\mathbf{p}|^z/\omega) \quad (22)$$

where Δ_O is the scaling dimension of the observable O .

The situation changes at finite temperature T . A quantum field theory at temperature T is described by a path integral on a manifold, which, along the imaginary time direction τ , is finite of length $2\pi/T$ and periodic for a theory bosonic fields and antiperiodic for fermionic fields (Fradkin, 2021). Since the imaginary time direction is finite, the behavior for correlation times $\xi_\tau < 2\pi/T$ and $\xi_\tau > 2\pi/T$ must be different. Indeed, in the first regime, the behavior is essentially the same as at $T = 0$ while in the second, it should be given by the classical theory in the same space dimension. At the quantum critical point g_c , there is only one time scale $\xi_\tau \sim 2\pi/T$ and only one length scale $\xi \sim (2\pi/T)^{1/z}$.

The Ising model in a transverse field

The prototype of the quantum phase transition is the Ising model in a transverse field. This model describes a system of spin-1/2 degrees of freedom with ferromagnetic interactions with uniaxial anisotropy in the presence of a transverse uniform magnetic field. The Hamiltonian is

$$H = -J \sum_{\langle r, r' \rangle} \sigma_3(r) \sigma_3(r') - h \sum_r \sigma_1(r) \quad (23)$$

where J and h are the exchange coupling constant and the strength of the transverse field, respectively. Here, σ_1 and σ_3 are the two Pauli matrices defined on the sites $\{r\}$ of a lattice with ferromagnetic interactions between spins on nearest neighboring sites. The Hilbert space is the tensor product of the states of the spins at each site of the lattice. At each site, there are two natural bases of states: the eigenstates of σ_3 , which we denote by $|\uparrow\rangle$ and $|\downarrow\rangle$ (whose eigenvalues are ± 1), and the eigenstates of σ_1 , which we denote by $|\pm\rangle$ (whose eigenvalues are also ± 1).

It is well known that the Ising model in a transverse field on a hypercubic lattice in D dimensions is equivalent to a classical Ising model in $D + 1$ dimensions (Fradkin and Susskind, 1978; Kogut, 1979). These two models are related through the transfer matrix. Indeed, a classical Ising model can be regarded as a path integral representation of the quantum model in one dimension less. For simplicity we will see how this works for the 2D classical ferromagnetic Ising model of Eq. (1), but the construction is general. We will regard the configuration of spins on a row of the 2D lattice as a state of a quantum system, and the set of states on all rows as the evolution of the state along the perpendicular direction that we will regard as a discretized imaginary time. The contribution from two adjacent rows to the partition function defines the matrix element of a matrix between two arbitrary configurations. In Statistical Physics, this matrix is known as the transfer matrix $\hat{T}$ and the full partition function (with periodic boundary conditions) is

$$Z = \text{tr} \hat{T}^{N_\tau} \quad (24)$$

where N_τ is the number of rows. For the case of the ferromagnetic Ising model (actually, for any unfrustrated model), the transfer matrix can always be constructed to be Hermitian. This property holds in fact for any theory that satisfies a property known as reflection positivity which requires that all (suitably defined) correlation functions be positive. For theories of this type, and the Ising model is an example, the matrix elements of the transfer matrix can be identified with the matrix element of the evolution operator of a quantum theory for a small imaginary time step (Fradkin and Susskind, 1978). Also, the positivity of the correlators is equivalent to the condition of positivity of the norm of states in the quantum theory.

For the classical models that satisfy these properties, all directions of the lattice are equivalent. Moreover, asymptotically close to the critical point, the behavior of all the correlators becomes isotropic, that is, invariant under the symmetries of Euclidean space. This means that the arbitrary choice of the direction for the transfer matrix is irrelevant. Consequently, in the quantum model, its equal-time correlators behave the same way as its correlation functions in imaginary time. In other words, space and time behave in the same way and the quantum theory is relativistically invariant. This implies at the quantum critical point the energy $\varepsilon(\mathbf{p})$ of its massless excitations should behave as $\varepsilon(\mathbf{p}) = v |\mathbf{p}|$. In a relativistic theory the dynamical critical exponent must be $z = 1$ and the coefficient v is the speed of the excitations (the “speed of light”). We should note that this is not necessarily always the case. There are in fact classical systems, for example, liquid crystals (Chaikin and Lubensky, 1995), which are spatially anisotropic and map onto quantum mechanical theories in one less dimension for which the dynamical critical exponent $z \neq 1$. One such example are the Lifshitz transitions of nematic liquid crystals in three dimensions and the associated quantum Lifshitz model in $D = 2$ dimensions, for which the dynamical exponent is $z = 2$ (Ardonne et al., 2004).

Just as in the classical counterpart in $D + 1$ dimensions, the quantum model in $D \geq 1$ has two phases: a broken symmetry ferromagnetic phase for $J \gg h$ and a symmetric paramagnetic phase for $h \gg J$. In the symmetric phase, the ground state is unique (asymptotically is the eigenstate of σ_1 with eigenvalue $+1$) while in the broken symmetry phase, the ground state is doubly degenerate (and asymptotically is an eigenstate of σ_3) and there is a nonvanishing expectation value of the local order parameter $\langle \sigma_3(r) \rangle \neq 0$. In the symmetric phase, the correlation function of the local order parameter decays exponentially with distance with a correlation length ξ , as does the connected correlation function in the broken symmetry phase. The model has a continuous quantum phase transition at a critical value of the ratio h/J . For general space dimensions $D > 1$, this model is not exactly solvable and much of what we know about it is due to large-scale numerical simulations.

This problem was solved exactly in one-dimension (Pfeuty, 1970) using the Jordan–Wigner transformation that maps a one-dimensional quantum spin system to a theory of free fermions (Lieb et al., 1961). The fermion operators at site j are

$$\chi_1(j) = K(j-1)\sigma_3(j), \quad \chi_2(j) = i\hat{K}(j)\sigma_3(j) \quad (25)$$

where $K(j)$ is the kink creation operator (i.e., the operator that creates a domain wall between sites j and $j+1$ (Fradkin and Susskind, 1978), and is given by

$$K(j) = \prod_{n \leq j} \sigma_1(n) \quad (26)$$

The operators $\chi_1(j)$ and $\chi_2(j)$ are Hermitian, $\chi_j^\dagger(n) = \chi_j(n)$ and obey the *anticommutation* algebra

$$\{\chi_j(n), \chi_{j'}(n')\} = 2\delta_{jj'}\delta_{nn'}. \quad (27)$$

Hence, they are fermionic operators and are Hermitian, anticommute with each other and square to the identity. Operators of this type are called *Majorana fermions*.

Alternatively, we can use the more conventional (Dirac) fermion operators $c(n)$ and its adjoint $c^\dagger(n)$ which are related to the Majorana fermions as

$$c(n) = \chi_1(n) + i\chi_2(n), \quad c^\dagger(n) = \chi_1(n) - i\chi_2(n) \quad (28)$$

which obey the standard anticommutation algebra

$$\{c(n), c(n')\} = \{c^\dagger(n), c^\dagger(n')\} = 0, \quad \{c(n), c^\dagger(n')\} = \delta - nn'. \quad (29)$$

In this sense, a Majorana fermion is half of a Dirac fermion.

In terms of the Majorana operators, the Hamiltonian of Eq. (23) becomes

$$H = i \sum_j \chi_1(j) \chi_2(j) + ig \sum_j \chi_2(j) \chi_1(j+1) \quad (30)$$

where we have rescaled the Hamiltonian by a factor of $\hbar$ and the coupling constant is $g = J/\hbar$. Here, we have not specified the boundary conditions (which depend on the fermion parity). Qualitatively, the Majorana fermions can be identified with the domain walls of the classical models. In the Ising model, the number of domain walls on each row is not conserved but their parity is. Likewise, the number of Majorana fermions N_F is not conserved either but the fermion parity $(-1)^{N_F}$ is conserved.

It is an elementary exercise to show that the spectrum of this theory has a gap $G(g)$ that vanishes at $g_c = 1$ as $G(g) \sim |g - g_c|^\nu$, with an exponent $\nu = 1$. Since the Hamiltonian of Eq. (30) is quadratic in the Majorana operators, these operators obey linear equations of motion. In the scaling regime, we take the limit of the lattice spacing $a \rightarrow 0$ and the coupling constant $g \rightarrow g_c = 1$ while keeping the quantity $m = (g - g_c)/a$ fixed. In this regime, the two-component Hermitian spinor field $\chi = (\chi_1, \chi_2)$, and $\chi^\dagger = \chi$, satisfies a Dirac equation

$$(i\partial - m)\chi = 0 \quad (31)$$

where we set the speed $v = 1$, and defined the 2×2 Dirac gamma-matrices $\gamma_0 = \sigma_2$, $\gamma_1 = i\sigma_3$, and $\gamma_5 = \sigma_1$. Upon defining $\bar{\chi} = \chi^T \gamma_0$, we find that the Lagrangian of this field theory is

$$\mathcal{L} = \bar{\chi} i \partial \chi - \frac{1}{2} m \bar{\chi} \chi \quad (32)$$

which indeed becomes massless at the quantum phase transition of the Ising spin chain. For these considerations, we say that the phase transition of the Ising model (2D classical or 1D quantum) is in the universality class of massless Majorana fermions where $m \rightarrow 0$. In Eq. (32), we have used the standard Feynman slash notation, $\not{a} = \gamma_\mu a^\mu$, where a^μ is a vector.

Quantum antiferromagnets and nonlinear sigma models

As we noted above, the discovery of high temperature superconductors in the copper oxide compounds prompted the study of the behavior of these strongly correlated materials at low temperatures and of possible quantum phase transitions which they may host. The prototypical cuprate material La_2CuO_4 is a quasi two-dimensional Mott insulator that exhibits long-range antiferromagnetic order below a critical temperature T_c . A simple microscopic model is a spin-S quantum Heisenberg antiferromagnet on the 2D square lattice of the Cu atoms, whose Hamiltonian is

$$H = \frac{1}{2} \sum_{\mathbf{r}, \mathbf{r}'} J(|\mathbf{r} - \mathbf{r}'|) \mathbf{S}(\mathbf{r}) \cdot \mathbf{S}(\mathbf{r}') \quad (33)$$

where $\mathbf{S}$ are the spin-S angular momentum operators. We will consider the case where the exchange interaction for nearest neighbors J is dominant and a weaker $J' \ll J$ for next nearest neighbors. In this section we do not consider the regime $J' \simeq J$ in which the interactions compete for incompatible ground states due to frustration effects.

Spin coherent states

The simplest way to see the physics of this antiferromagnet is to construct a path-integral representation for a spin-S system using spin coherent states (Perelomov, 1986; Fradkin and Stone, 1988; Wiegmann, 1989). For details, see Fradkin (2013) which we follow here. A coherent state of the $(2S + 1)$ -dimensional spin-S representation of $SU(2)$ is the state $|\mathbf{n}\rangle$, labeled by the spin polarization unit vector $\mathbf{n}$

$$|\mathbf{n}\rangle = e^{i\theta(\mathbf{n}_0 \times \mathbf{n}) \cdot \mathbf{S}} |S, S\rangle \quad (34)$$

where $\mathbf{n}^2 = 1$. The states of the spin-S representation are spanned by the eigenstates of S_3 and S^2 ,

$$S_3 |S, M\rangle = M |S, M\rangle, \quad S^2 |S, M\rangle = S(S+1) |S, M\rangle \quad (35)$$

and $|S, S\rangle$ is the highest weight state with eigenvalues S and $S(S+1)$. In Eq. (34), $\mathbf{n}_0$ is a unit vector along the axis of quantization (the direction $\mathbf{e}_3$), and θ is the colatitude, such that $\mathbf{n} \cdot \mathbf{n}_0 = \cos \theta$. Two spin coherent states, $|\mathbf{n}_1\rangle$ and $|\mathbf{n}_2\rangle$, are not orthonormal,

$$\langle \mathbf{n}_1 | \mathbf{n}_2 \rangle = e^{i\Phi(\mathbf{n}_1, \mathbf{n}_2, \mathbf{n}_0)} S \left(\frac{1 + \mathbf{n}_1 \cdot \mathbf{n}_2}{2} \right)^S \quad (36)$$

where $\Phi(\mathbf{n}_1, \mathbf{n}_2, \mathbf{n}_0)$ is the area of the spherical triangle of the unit sphere spanned by the unit vectors $\mathbf{n}_1$, $\mathbf{n}_2$, and $\mathbf{n}_0$. However, there is an ambiguity in the definition of the area of the spherical triangle since the sphere is a 2-manifold without boundaries: if the “inside” triangle has spherical area Φ , the complement (“outside”) triangle has area $4\pi - \Phi$. Thus, the ambiguity of the phase prefactor of Eq. (36) is

$$e^{i4\pi S} = 1 \quad (37)$$

since S is an integer or a half-integer. So, the quantization of the representations of $SU(2)$ makes the ambiguity unobservable. In addition, the spin coherent states $|\mathbf{n}\rangle$ satisfy the resolution of the identity

$$I = \int |\mathbf{n}\rangle \langle \mathbf{n}| \left(\frac{2S+1}{4\pi} \right) \delta(\mathbf{n}^2 - 1) d^3 n \quad (38)$$

and

$$\langle \mathbf{n} | S | \mathbf{n} \rangle = S n \quad (39)$$

Path integral for a spin- S degree of freedom

As an example, consider problem of a spin- S degree of freedom coupled to an external magnetic field $\mathbf{B}(t)$ that varies slowly in time. The (time-dependent) Hamiltonian is given by the Zeeman coupling

$$H(t) = \mathbf{B}(t) \cdot \mathbf{S} \quad (40)$$

As usual, the path integral is obtained by inserting the (over-complete) set of coherent states at a large number of intermediate times. The resulting path integral is a sum of the histories of the spin polarization vector $\mathbf{n}(t)$

$$Z = \text{tr} \exp \left(i \int_0^T dt H(t) \right) = \int \mathcal{D}\mathbf{n} \exp(iS[\mathbf{n}]) \prod_t \delta(\mathbf{n}^2(t) - 1) \quad (41)$$

where the action is

$$S = S_{WZ}[\mathbf{n}] - S \int_0^T dt \mathbf{B}(t) \cdot \mathbf{n}(t) \quad (42)$$

where $S_{WZ}[\mathbf{n}]$ is the Wess–Zumino action

$$S_{WZ}[\mathbf{n}] = \int_0^T dt \mathbf{A}[\mathbf{n}] \cdot \partial_t \mathbf{n} \quad (43)$$

$$= \int_0^1 d\tau \int_0^T dt \mathbf{n}(t, \tau) \cdot \partial_t \mathbf{n}(t, \tau) \times \partial_\tau \mathbf{n}(t, \tau) \quad (44)$$

where $\mathbf{A}[\mathbf{n}]$ is the vector potential of a Dirac magnetic monopole (of unit magnetic charge) at the center of the unit sphere. The vector potential $\mathbf{A}[\mathbf{n}]$ has a singularity associated with the Dirac string of the monopole. We can write an equivalent expression that is singularity-free using Stokes Theorem. We did this in the second line of Eq. (44) which required to extend the circulation of $\mathbf{A}$ on the closed path described by $\mathbf{n}(t)$ to the flux of the vector potential through the submanifold Σ of the unit sphere S_2 whose boundary is the history $\mathbf{n}(t)$, that is, the area of Σ . The smooth (and arbitrary) extension of configuration $\mathbf{n}(t)$ to the interior of Σ is done by defining $\mathbf{n}(t, \tau)$ such that $\mathbf{n}(t, 1) = \mathbf{n}_0$, $\mathbf{n}(t, 0) = \mathbf{n}(t)$, and $\mathbf{n}(0, \tau) = \mathbf{n}(T, \tau)$. Since S_{WZ} is the area of the submanifold Σ of the unit sphere S_2 , just as in Eq. (37), here too there is an ambiguity of 4π in the definition of the area. Here too, this ambiguity is invisible since the spin S is an integer or a half-integer.

The path integral of Eq. (41) was derived first by [Berry \(1984\)](#) (and extended by [Simon \(1983\)](#)). The first term (which we called Wess–Zumino by analogy with its field theoretic versions) is called the *Berry Phase*. The role of this term, which is first order in time derivatives, is to govern the quantum dynamics of the spin which, in the presence of a uniform magnetic field, executes a precessional motion of the (Bloch) sphere. It is also apparent from this expression that in the large- S limit, the path integral can be evaluated by means of a semiclassical approximation.

The coherent-state construction shows that this problem is equivalent to the path integral of a formally massless nonrelativistic particle of unit electric charge on the surface of the unit sphere with a magnetic monopole of magnetic charge S in its interior! This is not surprising since the Hilbert space of a nonrelativistic particle moving on the surface of a sphere with and radial magnetic field (the field of a magnetic monopole) has a Landau level-type spectrum with a degeneracy given by the flux. The condition of a massless particle means that only the lowest Landau level survives and all other levels have an infinite energy gap.

The coherent state approach has been used to derive a path integral formulation for ferromagnets and antiferromagnets. A detailed derivation can be found in [Fradkin \(2013\)](#).

Quantum ferromagnet

We will consider first the simpler case of a quantum ferromagnet and in Eq. (33) we will set $J = -|J| < 0$ for nearest neighbors and zero otherwise. The action for the path integral for the spin- S quantum Heisenberg ferromagnet on a hypercubic lattice is

$$\mathcal{S} = S \sum_{\mathbf{r}} \mathcal{S}_{\text{WZ}}[\mathbf{n}(\mathbf{r}, t)] - \frac{|J|S^2}{2} \sum_{\langle \mathbf{r}, \mathbf{r}' \rangle} \int_0^T dt (\mathbf{n}(\mathbf{r}, t) - \mathbf{n}(\mathbf{r}', t))^2 \quad (45)$$

where we have subtracted the classical ground state energy. The order parameter for this theory is the expectation value of the local magnetization, $\mathbf{n} = \langle \mathbf{n}(\mathbf{r}) \rangle$, which is constant in space but points in an arbitrary direction in spin space.

In the low-energy regime, the important configurations are slowly varying in space and we can simply approximate the action of Eq. (45) by its continuum version in d space dimensions

$$\mathcal{S} = \frac{S}{a_0^d} \int d^d x \mathcal{S}_{\text{WZ}}[\mathbf{n}(\mathbf{x}, t)] - \frac{|J|S^2}{2a_0^d} \int d^d x \int_0^T dt (\nabla \mathbf{n}(\mathbf{x}, t))^2 \quad (46)$$

where a_0 is the lattice spacing. As before, the path integral is done for a field, which satisfies everywhere in space-time the constraint $\mathbf{n}^2(\mathbf{x}, t) = 1$. This action can be regarded as nonrelativistic nonlinear sigma model.

It is straightforward to show that the classical equations of motion for this theory are the Landau–Lifshitz equations

$$\partial_t \mathbf{n} = |J|Sa_0^2 \mathbf{n} \times \nabla^2 \mathbf{n} \quad (47)$$

subject to the constraint $\mathbf{n}^2 = 1$. Due to the constraint, the Landau–Lifshitz equation is nonlinear. We will decompose the field into a longitudinal and two transverse components, σ and $\boldsymbol{\pi}$, respectively

$$\mathbf{n} = \begin{pmatrix} \sigma \\ \boldsymbol{\pi} \end{pmatrix} \quad (48)$$

subject to the constraint $\sigma^2 + \boldsymbol{\pi}^2 = 1$. The linearized Landau–Lifshitz equations become (to linear order in $\boldsymbol{\pi}$)

$$\partial_t \pi_1 \simeq -|J|Sa_0^2 \nabla^2 \pi_2, \quad \partial_t \pi_2 \simeq +|J|Sa_0^2 \nabla^2 \pi_1 \quad (49)$$

The solution to these equations are ferromagnetic spin waves (magnons or Bloch waves) which satisfy the dispersion relation

$$\omega(\mathbf{p}) \simeq |J|Sa_0^2 \mathbf{p}^2 + O(\mathbf{p}^4) \quad (50)$$

which shows that the dynamic exponent for a ferromagnet is $z = 2$. Notice that in this case the two transverse components are not independent (they are effectively a dynamical pair). These are the Goldstone bosons of a ferromagnet.

Quantum antiferromagnet

Formally, the quantum antiferromagnet has a coherent state path integral whose action is

$$\mathcal{S} = S \sum_{\mathbf{r}} \mathcal{S}_{\text{WZ}}[\mathbf{n}(\mathbf{r}, t)] - \frac{JS^2}{2} \sum_{\langle \mathbf{r}, \mathbf{r}' \rangle} \int_0^T dt \mathbf{n}(\mathbf{r}, t) \cdot \mathbf{n}(\mathbf{r}', t) \quad (51)$$

with $J > 0$. For a bipartite lattice, for example, the 1D chain, and the square and cubic lattices, the classical ground state is an antiferromagnet with a Néel order parameter, the staggered magnetization. Let $\mathbf{m}(\mathbf{r})$ be the expectation value of the local magnetization. A bipartite lattice is the union of two interpenetrating sublattices, and the local magnetization is staggered, that is, it takes values with opposite signs (with equal values) on the two sublattices. Thus, we make the change of variables, $\mathbf{n}(\mathbf{r}, t) \rightarrow (-1)^{\mathbf{r}} \mathbf{n}(\mathbf{r}, t)$ in Eq. (51) and find

$$\mathcal{S} = S \sum_{\mathbf{r}} (-1)^{\mathbf{r}} \mathcal{S}_{\text{WZ}}[\mathbf{n}(\mathbf{r}, t)] - \frac{JS^2}{2} \sum_{\langle \mathbf{r}, \mathbf{r}' \rangle} \int_0^T dt (\mathbf{n}(\mathbf{r}, t) - \mathbf{n}(\mathbf{r}', t))^2 \quad (52)$$

We want to obtain the low energy effective action for the field $\mathbf{n}(\mathbf{r}, t)$. To this end, we decompose this field into a slowly varying part, that we will call $\mathbf{m}(\mathbf{r}, t)$, and a small rapidly varying part $\mathbf{l}(\mathbf{r}, t)$ (which represents ferromagnetic fluctuations)

$$\mathbf{n}(\mathbf{r}, t) = \mathbf{m}(\mathbf{r}, t) + (-1)^{\mathbf{r}} a_0 \mathbf{l}(\mathbf{r}, t) \quad (53)$$

Since $\mathbf{n}^2(\mathbf{r}, t) = 1$, we will demand that the slowly varying part also obeys the constraint, $\mathbf{m}^2(\mathbf{r}, t) = 1$, and require that the two components be orthogonal to each other, $\mathbf{m} \cdot \mathbf{l} = 0$.

Due to the behavior of the staggered Wess–Zumino terms of Eq. (52), the resulting continuum field theory turns out to have subtle but important differences between one dimension and higher dimensions. Here we will state the results for two and higher dimensions. We will discuss in detail the one-dimensional below when we discuss the role of topology.

It turns out that if the dimension $d > 1$, the contribution of the staggered Wess–Zumino terms for *smooth* field configurations is (Fradkin and Stone, 1988; Dombre and Read, 1988; Haldane, 1988b)

$$\lim_{a_0 \rightarrow 0} S \sum_r (-1)^r \mathcal{S}_{\text{WZ}}[\mathbf{n}(\mathbf{r}, t)] = S \int d^3x \mathbf{l}(\mathbf{x}, t) \cdot \mathbf{m}(\mathbf{x}, t) \times \partial_t \mathbf{m}(\mathbf{x}, t) \quad (54)$$

The continuum limit of the second term of Eq. (52) in the case of a two-dimensional system is

$$\lim_{a_0 \rightarrow 0} \frac{JS^2}{2} \sum_{\langle \mathbf{r}, \mathbf{r}' \rangle} \int_0^T dt (\mathbf{n}(\mathbf{r}, t) - \mathbf{n}(\mathbf{r}', t))^2 = a_0 \frac{JS^2}{2} \int d^3x ((\nabla \mathbf{m}(\mathbf{x}, t))^2 + 4I^2(\mathbf{x}, t)). \quad (55)$$

The massive field $\mathbf{l}[\mathbf{x}, t]$ represents ferromagnetic fluctuations. Since this is a massive field, it can be integrated out leading to an effective field theory for the *antiferromagnetic* fluctuations $\mathbf{m}(\mathbf{x}, t)$ whose Lagrangian is that of a nonlinear sigma model

$$\mathcal{L} = \frac{1}{2g} \left(\frac{1}{v_s} (\partial_t \mathbf{m}(\mathbf{x}, t)) - v_s (\nabla \mathbf{m}(\mathbf{x}, t))^2 \right) \quad (56)$$

where the coupling constant is $g = 2/S$ and the spin-wave velocity is $v_s = 4a_0JS$. If we allow for a weak next-nearest-neighbor interaction $J' > 0$, the coupling constant g and the spin wave velocity v_s become renormalized to $g' \simeq g/\sqrt{1 - 2J'/J}$ and $v'_s \simeq v_s \sqrt{1 - 2J'/J}$.

We conclude that the quantum fluctuations about a Néel state are well described by a nonlinear sigma model. Provided the frustration effects of the next-nearest-neighbor interactions are weak enough, the long-range antiferromagnetic Néel order should extend up to a critical value of the coupling constant g_c where the RG beta function has a nontrivial zero, which signals a quantum phase transition to a strong coupling phase without long-range antiferromagnetic order.

Motivated by the discovery of high temperature superconductivity in the strongly correlated quantum antiferromagnet La_2CuO_4 (at finite hole doping) in 1988, Chakravarty et al. (1988) utilized a quantum nonlinear sigma model to analyze this system and its quantum phase transition. La_2CuO_4 is a quasi-two-dimensional material and so it exhibits strong quantum and thermal fluctuations. The upshot of this analysis is that while at $T = 0$ the nonlinear sigma model has a quantum phase transition, at $T > 0$, the long-range order is absent in a strictly 2D system but present in the actual material due to the weak-three-dimensional interaction. So, in the strict 2D case, there is no phase transition but two different *crossover* regimes: a renormalized classical regime (without long-range order), a quantum disordered regime and a quantum critical regime. La_2CuO_4 has long-range Néel (antiferromagnetic) order at $T = 0$ and is in the renormalized classical regime (with long-range order due to the weak 3D interaction).

The nonlinear sigma model does not describe the nature of the ground state for $g > g_c$ beyond saying that there is no long-range order. The problem is that, unlike the Ising model in a transverse field, the microscopic tuning parameter is the next nearest neighbor antiferromagnetic coupling J' , and to reach the regime $g \simeq g_c$, one has to make $J' \simeq J$. This is the regime in which frustration effects become strong. In this regime, the assumption that the important configurations are smooth and close to the classical Néel state is incorrect. The nature of the ground state turns out to depend on the value of S .

Topological excitations

Topology has come to play a crucial role both in condensed matter physics and in Quantum Field Theory. Topological concepts have been used to classify topological excitations such as vortices and dislocations and to provide a mechanism for phase transitions, quantum number fractionalization, tunneling processes in field theories, and nonperturbative construction of vacuum states. Here, we will discuss a few representative cases of what has become a very vast subject.

Topological excitations: Vortices and magnetic monopoles

In condensed matter physics, topological excitations play a central role in the description of topological defects and on their role in phase transitions. Here, topology integers in the classification of the configuration space into equivalence classes characterized by topological invariants (Mermin, 1979). The most studied example is vortices. Vortices play a key role in the mixed phase of type II superconductors in a uniform magnetic field (Abrikosov, 1957). Vortices also play a key role in the Statistical Mechanics of 2D superfluids and the 2D classical XY model (Kosterlitz and Thouless, 1973; Kosterlitz, 1974; Berezinskii, 1971, 1972; José et al., 1977). Dislocations and disclinations play an analogous role in the theory of classical melting (Kosterlitz and Thouless, 1973; Halperin and Nelson, 1978; Young, 1979), and 2D and 3D classical liquid crystals (Toner and Nelson, 1981; Nelson and Toner, 1981; Chaikin and Lubensky, 1995).

A similar problem occurs in Quantum Field Theory. Theories with global symmetries, such as the two-dimensional $O(3)$ nonlinear sigma model discussed above, when formulated in Euclidean space-time have *instantons*. Typically, instantons are finite Euclidean action configurations, which are also classified into equivalence classes (associated with homotopy groups) labeled by topological invariants (Coleman, 1985; Rajaraman, 1985). Instantons play a central role in understanding the nonperturbative structure of gauge theories. Gauge theories with a compact gauge group coupled to matter fields have nontrivial vortex (Nielsen and Olesen, 1973) and monopole ('t Hooft, 1976b; Polyakov, 1977, 1987) configurations, as do non-Abelian Yang–Mills gauge theories (Callan et al., 1976). Instantons have also played a central role in condensed matter physics as well, notably in Haldane's

work on 1D quantum antiferromagnets (discussed below), and in the problem of macroscopic quantum tunneling and coherence (Caldeira and Leggett, 1983; Leggett et al., 1987).

Vortices in two dimensions

In this section, I will focus on the problem of the superfluid transition in 2D and the closely related problem of the phase transition of a magnet with an easy-plane anisotropy, the classical XY model. A superfluid is described by an order parameter that is a one-component complex field $\phi(\mathbf{x})$. If electromagnetic fluctuations are ignored, this description also applies to a superconductor. The complex field can be written in terms of an amplitude $|\phi(\mathbf{x})|$, whose square represents the local superfluid density, and a phase $\theta(\mathbf{x}) = \arg(\phi(\mathbf{x}))$. Deep in the superfluid phase, the amplitude is essentially constant, that we will set to be a real positive number ϕ_0 , while the phase field $\theta(\mathbf{x})$ is periodic with period 2π and can fluctuate. Similarly, an easy-plane ferromagnet is described by a two-component real order parameter field $\mathbf{M}(\mathbf{x}) = (M_1(\mathbf{x}), M_2(\mathbf{x})) = |\mathbf{M}(\mathbf{x})|(\cos \theta(\mathbf{x}), \sin \theta(\mathbf{x}))$. Deep in the ferromagnetic phase, the amplitude $|\mathbf{M}|$ is essentially constant but the phase field $\theta(\mathbf{x})$ can fluctuate.

We will assume that we are in a regime where the local superfluid density $|\phi_0|^2$ is well formed (or, equivalently that $|\mathbf{M}|$ is locally well formed) but that the phase field is fluctuating. In this regime, the problem at hand is an $O(2) \simeq U(1)$ nonlinear sigma model, and its partition function takes the form

$$Z = \int \mathcal{D}\theta \exp\left(-\int d^2x \frac{1}{2g} (\partial_\mu \theta(\mathbf{x}))^2\right) \quad (57)$$

where we defined the coupling constant $g = T/J|\phi_0|^2$, where T is the temperature, J is an interaction strength, and $|\phi_0|^2$ is the magnitude (squared) of the amplitude of the order parameter, which we will take to be constant; $\kappa = J|\phi_0|^2$ is the phase stiffness.

Except for the requirement that the phase field be *locally* periodic, $\theta \simeq \theta + 2\pi$, superficially this seems to be a trivial free (Gaussian) field theory. We will see that the periodicity (or, *compactification*) condition makes this theory nontrivial. Indeed, configurations of the phase field that are weak enough and do not see the periodicity condition, can for all practical purposes, be regarded as being noncompact and ranging from $-\infty$ to $+\infty$. However there are many configurations for which the periodicity condition is essential. Such configurations are called *vortices*.

Even in the absence of vortices, the periodic (compact) nature of the phase field is essential to the physics of this problem. In fact the only allowed observables must be invariant under local periodic shifts of the phase field. This implies that the phase field θ itself is not a physical observable but that exponentials of the phase of the form $\exp(in\theta(\mathbf{x}))$ are physical. This operator is just the order parameter field of the XY model. In CFT, operators of this type are called vertex operators (Di Francesco et al., 1997; Ginsparg, 1989). We will see below that this theory has a dual field ϑ , associated with vortices, and that there are vertex operators of the dual field. In String Theory, the model of a compactified scalar is known as the compactified boson and represents the coordinate of a string on a compactified space, in this case a circle S_1 (Polchinski, 1998).

To picture a vortex, consider a large closed curve C on the 2D plane. Hence, topologically a closed curve is isomorphic to a circle, $C \simeq S_1$. The phase field $\theta(\mathbf{x})$ is equivalent to a unit circle S_1 . Therefore the configuration space are maps of S_1 (the large circle) onto S_1 (the unit circle of the order parameter space). The configurations can be classified by the number of times the phase winds on the large circle C . The winding number is an integer called the topological charge of the configuration, the vorticity. Thus, a vortex is a configuration of the phase field $\theta(\mathbf{x})$ that winds by $2\pi m$ (where m is an integer):

$$\frac{(\Delta\theta)_C}{2\pi} = \frac{1}{2\pi} \oint_C d\mathbf{x} \cdot \nabla \theta(\mathbf{x}) \equiv i \oint_0^{2\pi} \frac{d\varphi}{2\pi} e^{i\theta(\varphi)} \partial_\varphi e^{-i\theta(\varphi)} = m \quad (58)$$

where $\varphi \in (0, 2\pi]$ is the azimuthal angle for a vector at the center of the large circle C . Here n is the vorticity or *winding number* of the configuration; $m > 0$ is a vortex and $m < 0$ is an antivortex. The vorticity is a *topological invariant* of the field the configuration $\theta(\mathbf{x})$ which does not change under smooth changes.

The winding number of a vortex is a topological invariant that classifies the configurations of the phase field as continuous maps of a large circle S_1 onto the unit circle S_1 defined by the phase field. In topology such continuous maps are called homotopies. The winding number classifies these maps into a discrete set of equivalence classes, which form a *homotopy group* under the composition of two configurations. In this case, the homotopy group is called $\Pi_1(S_1)$. Since the equivalence classes are classified by a topological invariant that takes integer values, the homotopy group $\Pi_1(S_1)$ is isomorphic to the group of integers, $\mathbb{Z}$ (Mermin, 1979).

The field $j_\mu(\mathbf{x}) = \partial_\mu \theta(\mathbf{x})$ is the superfluid current, and the *vorticity* $\omega(\mathbf{x})$ is the curl of the current, that is,

$$\omega(\mathbf{x}) = \epsilon_{\mu\nu} \partial_\mu j_\nu(\mathbf{x}) = \epsilon_{\mu\nu} \partial_\mu \partial_\nu \theta(\mathbf{x}) \quad (59)$$

which vanishes unless $\theta(\mathbf{x})$ has a branch-cut singularity across which the phase field jumps by $2\pi n$. Let $\omega(\mathbf{x})$ be the vorticity field with singularities at the locations $\{\mathbf{x}_j\}$ of vortices with topological charge m_j

$$\omega(\mathbf{x}) = 2\pi \sum_j m_j \delta^2(\mathbf{x} - \mathbf{x}_j) \quad (60)$$

which is satisfied by the phase field configuration

$$\theta(\mathbf{x}) = \sum_j 2\pi m_j \text{Im} \ln(z - z_j) \quad (61)$$

where we have used the complex coordinates $z = x_1 + ix_2$. Away from the singularities $\{x_j\}$, this configuration obeys the Laplace equation. Hence, it has a Cauchy–Riemann dual field $\vartheta(\mathbf{x})$, which satisfies the Cauchy–Riemann equation

$$\partial_\mu \vartheta = \varepsilon_{\mu\nu} \partial_\nu \theta \quad (62)$$

which satisfies the Poisson equation

$$-\nabla^2 \vartheta(\mathbf{x}) = \omega(\mathbf{x}) \quad (63)$$

whose solution is

$$\vartheta(\mathbf{x}) = \int d^2y G(|\mathbf{x} - \mathbf{y}|) \omega(\mathbf{y}) \quad (64)$$

where $G(|\mathbf{x} - \mathbf{y}|)$ is the Green function of the 2D Laplacian

$$-\nabla^2 G(|\mathbf{x} - \mathbf{y}|) = \delta^2(\mathbf{x} - \mathbf{y}). \quad (65)$$

In 2D, this Green function is

$$G(|\mathbf{x} - \mathbf{y}|) = \frac{1}{2\pi} \ln \left(\frac{a}{|\mathbf{x} - \mathbf{y}|} \right) \quad (66)$$

where a is a short distance cutoff (a lattice spacing). In what follows we will assume that the Green function of Eq. (66) has been cutoff so that $G(|\mathbf{x} - \mathbf{y}|) = 0$ for $|\mathbf{x} - \mathbf{y}| \leq a$.

The energy of a configuration of vortices $\{n_j\}$ with vanishing total vorticity, $\sum_j m_j = 0$, is

$$\begin{aligned} E[\theta] &= \frac{J\phi_0^2}{2} \int d^2x (\partial_\mu \theta)^2 \\ &= \frac{J\phi_0^2}{2} \int d^2x \int d^2y \omega(\mathbf{x}) G(|\mathbf{x} - \mathbf{y}|) \omega(\mathbf{y}) = 2\pi J\phi_0^2 \sum_{j>k} m_j m_k \ln \left(\frac{a}{|\mathbf{x}_j - \mathbf{x}_k|} \right) \end{aligned} \quad (67)$$

where we used that configurations with nonvanishing vorticity do not contribute to the partition function since they have infinite energy in the thermodynamic limit. We conclude that, up to an unimportant prefactor, the partition function of Eq. (57) is the same as the partition function a gas of charges $\{m_j\}$ (the vortices) with total vanishing vorticity, $\sum_j m_j = 0$,

$$Z_{2DCG} = \sum_{\{m_j\}} \exp \left(-2\pi \frac{J\phi_0^2}{T} \sum_{j>k} m_j m_k \ln \left(\frac{|\mathbf{x}_j - \mathbf{x}_k|}{a} \right) \right) \quad (68)$$

which is known as the two-dimensional (neutral) Coulomb gas (Kosterlitz and Thouless, 1973).

Kosterlitz and Thouless argued that the neutral two-dimensional Coulomb gas has a phase transition a critical temperature T_{KT} between a low temperature dielectric phase in which vortices and antivortices are bound into neutral pairs and a high temperature phase in which pairs unbind, the vortex charges are screened and the vortex gas is in a plasma phase. A simple estimate of the critical temperature is found by computing the free energy of a single vortex $F_{\text{vortex}} = E_{\text{vortex}} - TS_{\text{vortex}}$, where E_{vortex} is a single vortex and S_{vortex} is the vortex entropy. In 2D, the energy of a single vortex of unit topological charge, $n = 1$, is $\pi J\phi_0^2 \ln(L/a)$, where L is the linear size of the system, and the vortex entropy is $S_{\text{vortex}} = \ln(L/a)^2$, where $(L/a)^2$ is the number of places where a vortex can be located, that is, the area of the system in units of the spacing a . Vortices unbind (proliferate) when the entropy beats the energy. Hence, the critical point occurs at a temperature T_{KT} where the vortex free energy vanishes, $F_{\text{vortex}}[T_{KT}] = 0$. This yields the estimate

$$T_{KT} = \frac{\pi}{2} J\phi_0^2 \quad (69)$$

which is the Kosterlitz–Thouless critical temperature.

There is an alternative, equivalent way to see this physics. Let us consider the theory if Eq. (57) in the background of a $U(1)$ gauge field $A_\mu(x)$

$$Z[A] = \int \mathcal{D}\theta \exp \left(-\frac{1}{2g} \int d^2x (\partial_\mu \theta - A_\mu)^2 \right) \quad (70)$$

where the curl of the background gauge field A_μ is chosen to be equal to the local vorticity of Eq. (59),

$$\epsilon_{\mu\nu} \partial_\mu A_\nu(x) = \omega(x) \quad (71)$$

In other words, the gauge A_μ field forces the phase field to have vortices at the locations $\{x_j\}$.

Next we will use a Hubbard–Stratonovich transformation (a Gaussian identity) to write Eq. (70) in the equivalent form

$$Z[A] = \int \mathcal{D}\theta \int \mathcal{D}a_\mu \exp\left(-\frac{g}{2} \int d^2x a_\mu^2 + i \int d^2x a_\mu(x) (\partial_\mu \theta(x) - A_\mu(x))\right) \quad (72)$$

where we neglected an unimportant prefactor. In Eq. (72), the phase field can be integrated out (after an integration by parts) to yield the constraint $\partial_\mu a_\mu = 0$. This constraint is solved by introducing the dual field $\vartheta(x)$ such that

$$a_\mu(x) = \epsilon_{\mu\nu} \partial_\nu \vartheta(x) \quad (73)$$

Hence, the partition function $Z[A]$ becomes

$$Z[A] = \int \mathcal{D}\vartheta \exp\left(-\frac{g}{2} \int d^2x (\partial_\mu \vartheta)^2 + i \int d^2x \vartheta(x) \omega(x)\right) \quad (74)$$

where we have assumed that the total vorticity is zero, $\int d^2x \omega(x) = 2\pi \sum_j m_j = 0$. This identity shows that the quantization of the vortex topological charge requires that the dual field ϑ should also be periodic (compact) with period 1.

It is elementary to see that after performing the gaussian integral over the field ϑ in Eq. (74) and summing over all vortex configurations (with total vanishing vorticity), we reproduce the partition function of the 2D neutral Coulomb gas (Kadanoff, 1978; Nienhuis, 1987). Thus, the theory of Eq. (70) defined in terms of the phase field θ and the theory of Eq. (74) are equivalent. This is an example of a *duality transformation* which amounts to the exchange of the fields

$$\theta \leftrightarrow \vartheta, \quad \text{and} \quad g \leftrightarrow 1/g \quad (75)$$

A more careful analysis done on the lattice shows that the dual field ϑ is defined on the dual of the square lattice (which is also a square lattice) (José et al., 1977; Kadanoff, 1978). In addition, by differentiating both the partition function of the phase field of Eq. (70) and the partition function of the dual field ϑ of Eq. (74) with respect to the background field A_μ , we obtain the duality identification of the currents

$$\frac{1}{g} \partial_\mu \theta \longleftrightarrow g \epsilon_{\mu\nu} \partial_\nu \vartheta \quad (76)$$

as an operator identity. This identity is the same form as the duality of forms in geometry. In this case, the dual of the current $\partial_\mu \theta$, which is a 1-form field, is another 1-form field, $\partial_\mu \vartheta$. In both cases, the field θ and its dual ϑ are associated with global symmetries. Later, we will encounter similar duality identifications but their content will be different in different dimensions. Moreover, running these identities backwards, it is easy to see that the insertion of the order parameter operator $\exp(ip\theta(x))$ (with p an integer), which acts as a *source* on the phase field θ , in the partition function is equivalent to minimally couple the dual field ϑ to a singular gauge field $B_\mu(x)$ whose curl is p at the location x . In other words, *charges are dual to vortices*.

We will now use the identity we derived in Eq. (74) to compute the full partition function, which is a sum over all vortex configurations. Now we will assume that the vortices have a large core energy (i.e., the energy associated with the short distance behavior of the Green function of Eq. (66)). For a vortex with unit topological charge, we will call this energy u , and for a vortex with charge m the core energy will be um^2 . The effects of the core energy can be accounted for in terms of a vortex fugacity $z = \exp(-un^2/T)$. The total partition function now is

$$Z = \sum_{\{m_j\}} \int \mathcal{D}\vartheta \exp\left(-\frac{g}{2} \int d^2x (\partial_\mu \vartheta)^2 + i \sum_j 2\pi m_j \vartheta(x_j) - \frac{u}{T} \sum_j m_j^2\right) \quad (77)$$

where, once again, we assumed global charge neutrality.

In the limit in which $z = \exp(-u/T) \ll 1$, only the vortices with the lowest topological charges $m = \pm 1$ contribute and, furthermore, they are dilute. In this limit we can perform over the configurations with the lowest topological charge and derive the effective field theory of the dual field ϑ :

$$Z_{\text{SG}} = \int \mathcal{D}\vartheta \exp\left(-\int d^2x \left(\frac{g}{2} (\partial_\mu \vartheta)^2 - v \cos(2\pi\vartheta)\right)\right) \quad (78)$$

which is known as the sine-Gordon field theory. The coupling constant of the sine-Gordon theory is $v = 2 \exp(-u/T)/a^2$, where a is the core size (the lattice spacing). Hence, the cosine operator of the sine-Gordon theory represents the effects of the vortices.

We can now analyze the role of vortices by looking at the renormalization group of the sine-Gordon theory. The first question is what is the scaling dimension of the cosine operator. This can be computed by looking at the vortex operator correlator in the theory with $v = 0$:

$$\langle \exp(i2\pi\vartheta(x)) \exp(-i2\pi\vartheta(y)) \rangle = \frac{\text{const.}}{|x - y|^{2\pi/g}} \quad (79)$$

which implies that the vortex scaling dimension is

$$\Delta_{\text{vortex}} = \frac{\pi}{g} \quad (80)$$

Eq. (12) implies that in $D = 2$ dimensions the operator is irrelevant if $\Delta > 2$, relevant for $\Delta < 2$ and marginal for $\Delta = 2$. Hence, vortices are marginal if $\Delta_{\text{vortex}} = 2$, which happens if $g = \pi/2$. This is the same as to say that the system is at the Kosterlitz–Thouless critical temperature $T = T_{KT}$. Hence, vortices are irrelevant if $T < T_{KT}$ and relevant for $T > T_{KT}$.

This RG analysis tells us that $T > T_{KT}$, when vortices proliferate, the coupling constant v flows to strong coupling to a regime where ϑ is pinned to an integer value and the theory is in a massive phase. In this phase the connected vortex correlator decays exponentially with distance, which is the same as to say that the vortex charge is screened. This is why in this phase the vortices proliferate. It can be shown that in this phase the correlator of the spins of the XY model, that is, the correlator of the vertex operator $\exp(i\theta(x))$, decays exponentially with distance and the system is in its disordered phase.

There is still the question of the nature of the phase with $T < T_{KT}$. The Mermin–Wagner Theorem (Mermin and Wagner, 1966) [and its generalizations by Hohenberg (1967) and Coleman (1973)] states that classical statistical mechanical systems with a global continuous symmetry group cannot undergo spontaneous symmetry breaking in space dimensions $D \leq 2$ (and quantum systems with space-time dimensions $D \leq 2$). Does this theory violate this the Mermin–Wagner Theorem? The answer is no. It is easy to see that in the phase in which the vortices are irrelevant, that is, for $T < T_{KT}$, the correlator of the order parameter operator is always a power law of the distance $|x - y|$,

$$\langle \exp(i\theta(x)) \exp(-i\theta(y)) \rangle = \frac{\text{const.}}{|x - y|^{8/2\pi}} \quad (81)$$

with an exponent that depends on temperature and satisfies

$$\frac{g}{2\pi} = \frac{T}{2\pi J \phi_0^2} \leq \frac{1}{4}. \quad (82)$$

In other words, the entire low temperature phase is not an ordered phase of matter since the correlator is not constant at long-distance. On the other hand, the correlators of the order parameter $\exp(i\theta)$ and of the vortices $\exp(i\vartheta)$ have a power-law behavior for $T < T_{KT}$, we conclude that in this temperature range, the system is scale invariant and that it has a line of critical points.

In summary, we succeeded in expressing the partition function as a sum over configurations of the topological excitations, the vortices. We succeeded in doing that because vortices are labeled by their coordinates on the plane. In addition, we found a nontrivial phase transition since the entropy and the energy both scale logarithmically with the linear size of the system or, equivalently, that vortices became marginally relevant at a critical temperature. This is the mechanism behind the Kosterlitz–Thouless transition.

One may ask if this construction is generic and the answer is no. As an example, consider the Abelian Higgs model in $D = 2$. This model has a complex scalar field minimally coupled to a Maxwell gauge field and, hence, its gauge group is $U(1)$. In the classical spontaneously broken phase, the gauge field becomes massive. In this phase the long-range coherence of the phase field of the vortices of the scalar field is screened at the scale of the penetration depth. As a result, the Euclidean action of the vortices is now finite. Furthermore, on longer scales the interaction energy between vortices becomes short ranged. Hence, instead of a 2D Coulomb gas, now one has a gas of particles (vortices and antivortices) with short-range interactions. In this case the entropy always dominates and the vortices proliferate (Schaposnik, 1978). This behavior is quite analogous to the restoration of symmetry by proliferation of domain walls in one-dimensional classical spin chains (Landau and Lifshitz, 1959) and to the analogous problem of tunneling in the path integral formulation of quantum mechanical double-well potentials (Coleman, 1985). As a caveat, we should note that, in spite of the obvious similarities, the 2D Abelian Higgs model does not describe correctly a 2D superconductor (i.e., a superconducting film) since the electromagnetic field is not confined to the film, and this renders the electromagnetic action nonlocal.

Magnetic monopoles in compact electrodynamics

Instantons are of great interest in Quantum Field Theory since they provide for a mechanism to understand the nonperturbative structure of these theories. For this reason, they have been used to understand the mechanisms of quark confinement and the role of quantum anomalies in non-Abelian gauge theories (Callan et al., 1976; Polyakov, 1977, 1987; 't Hooft, 1976a, b). Instantons in non-Abelian gauge theories are magnetic monopoles and the condensation of monopoles has long been argued to be the mechanism behind quark confinement.

The simplest non-Abelian gauge theory that has magnetic monopoles is the Georgi–Glashow (Georgi and Glashow, 1974). This model has a three-component real field ϕ and an $SU(2)$ Yang–Mills gauge field A_μ . In its Higgs phase, the scalar field ϕ acquires an expectation value which breaks the gauge symmetry group $SU(2)$ down to its diagonal $U(1)$ subgroup. Since $U(1) \subset SU(2)$, this Abelian gauge group is compact, meaning that its magnetic fluxes are quantized. Polyakov (1975a) and 't Hooft (1976a) showed that in 2+1, Euclidean dimensions have nonsingular instanton solutions which at long distances resemble the magnetic monopole originally proposed by Dirac (1931)

$$B_i(x) = \frac{q}{2} \frac{x_i}{|x|^2} - 2\pi q \delta_{i,3} \delta(x_1) \delta(x_2) \theta(-x_3) \quad (83)$$

The first term in Eq. (83) is the magnetic radial field of a monopole of magnetic charge q . The second term represents an infinitely long infinitesimally thin solenoid ending at the location of the monopole, $x = 0$, that supplies the quantized magnetic flux $2\pi q$. This singular term is known as the Dirac string. The string itself (and its orientation) is physically unobservable to any electrically charged particle that obeys the Dirac quantization condition, $qe = 2\pi$ (in units where $\hbar = c = 1$).

In the language of a lattice gauge theory (Wilson, 1975), a theory with a compact (i.e., periodic) $U(1)$ gauge fields on a $D = 3$ cubic lattice, describing a compact gauge field in $2 + 1$ dimensions. This theory should have instantons that resemble magnetic monopoles much in the same way as a theory with a compact global $U(1)$ symmetry has vortices. The simplest example is Polyakov's compact electrodynamics (Polyakov, 1977) whose partition function is

$$Z = \prod_{x, \mu} \int_0^{2\pi} \frac{dA_\mu(x)}{2\pi} \exp\left(\frac{1}{4e^2} \sum_{x, \mu, \nu} \cos(F_{\mu\nu}(x))\right) \quad (84)$$

where $F_{\mu\nu}(x) = \Delta_\mu A_\nu(x) - \Delta_\nu A_\mu(x) \equiv \sum_\mu A_\mu$ is the magnetic flux through the elementary plaquette labeled by a site x and a pair of directions, μ and ν , with $\mu = 1, 2, 3$. This theory is invariant under local gauge transformations $A_\mu(x) \rightarrow A_\mu(x) + \Delta_\mu \Phi(x)$ and it is also invariant under local periodic shifts of the gauge fields $A_\mu(x) \rightarrow A_\mu(x) + 2\pi \ell_\mu(x)$, where $\ell_\mu(x) \in \mathbb{Z}$. The plaquette flux operator satisfies the lattice version of the Bianchi identity that the product of exponentials of the flux on the faces of every elementary cube of the lattice is

$$\prod_{\text{cube faces}} e^{iF_{\mu\nu}(x)} = 1 \quad (85)$$

which says that the theory can have magnetic monopoles of integer magnetic charge.

We will analyze this theory following an approach analogous to what we used for vortices in Section "Vortices in two dimensions." To this end, we will consider the partition function

$$Z[B_{\mu\nu}] = \int \mathcal{D}A_\mu \exp\left(-\frac{1}{4e^2} \int d^3x (F_{\mu\nu}(x) - B_{\mu\nu}(x))^2\right) \quad (86)$$

where $F_{\mu\nu}(x) = \partial_\mu A_\nu - \partial_\nu A_\mu$ is the field strength of the Abelian $U(1)$ Maxwell gauge field A_μ . Here $B_{\mu\nu}(x)$ is an (antisymmetric) two-form background gauge field. The coupling constant of this theory is e^2 . Since A_μ is a connection, it has units of length^{-1} , and $F_{\mu\nu}^2$ is a dimension 4 field. Then, in $D = 3$ dimensions, e^2 has units of length^{-1} .

The theory is invariant under two local transformations, namely the usual invariance under gauge transformations

$$A_\mu(x) \rightarrow A_\mu(x) + \partial_\mu \Phi(x), \quad B_{\mu\nu}(x) \rightarrow B_{\mu\nu}(x) \quad (87)$$

where $\Phi(x)$ is an arbitrary smooth function of x . The presence of the background two-form field $B_{\mu\nu}$ now requires invariance under one-form gauge transformations

$$A_\mu(x) \rightarrow A_\mu(x) + a_\mu(x), \quad B_{\mu\nu}(x) \rightarrow B_{\mu\nu}(x) + \partial_\mu a_\nu - \partial_\nu a_\mu \quad (88)$$

The two-form gauge field $B_{\mu\nu}$ essentially represents the magnetic monopoles. Let $\{m_j\}$ be a configuration of monopoles of charges m_j with coordinates $\{x_j\}$, with total vanishing monopole charge, $\sum_j m_j = 0$. Let $\mathcal{M}(x)$ be the magnetic monopole density at x ,

$$\mathcal{M}(x) = 2\pi \sum_j m_j \delta^3(x - x_j) \quad (89)$$

which can be expressed as the curl of the two-form gauge field $B_{\mu\nu}$,

$$\mathcal{M}(x) = \frac{1}{2} \epsilon_{\mu\nu\lambda} \partial_\mu B_{\nu\lambda}(x) \quad (90)$$

We will proceed next much in the same way as in Eq. (72) and rewrite the partition function of Eq. (86) in terms of a two-form Hubbard–Stratonovich field $b_{\mu\nu}(x)$ such that

$$\begin{aligned} Z[B] &= \int \mathcal{D}A_\mu \int \mathcal{D}b_{\mu\nu} \exp\left(-\frac{e^2}{4} \int d^3x b_{\mu\nu}^2(x) + i \int d^3x \frac{1}{2} b_{\mu\nu}(x) [F_{\mu\nu}(x) - B_{\mu\nu}(x)]\right) \\ &= \int \mathcal{D}A_\mu \int \mathcal{D}b_{\mu\nu} \exp\left(-\frac{e^2}{4} \int d^3x b_{\mu\nu}^2(x) + i \int d^3x [A_\mu(x) \partial_\nu b_{\mu\nu}(x) - \frac{1}{2} b_{\mu\nu}(x) B_{\mu\nu}(x)]\right) \end{aligned} \quad (91)$$

Thus, the gauge field A_μ plays the role of a Lagrange multiplier field the enforces the constraint

$$\partial_\nu b_{\mu\nu}(x) = 0 \quad (92)$$

which is solved in terms of a compact scalar field $\vartheta(x)$

$$b_{\mu\nu}(x) = \epsilon_{\mu\nu\lambda} \partial_\lambda \vartheta(x) \quad (93)$$

Using this identity and the definition of the monopole density $\mathcal{M}(x)$ we find that the partition function $Z[B_{\mu\nu}]$ of Eq. (86) becomes

$$\begin{aligned} Z[B] &= \int \mathcal{D}\vartheta \exp\left[-\int d^3x \left(\frac{e^2}{2} (\partial_\mu \vartheta(x))^2 + i \mathcal{M}(x) \vartheta(x)\right)\right] \\ &= \int \mathcal{D}\vartheta \exp\left[-\frac{e^2}{2} \int d^3x (\partial_\mu \vartheta(x))^2 + 2\pi i \sum_j m_j \vartheta(x_j)\right] \end{aligned} \quad (94)$$

which requires that the field ϑ obeys the compactification condition $\vartheta \rightarrow \vartheta + n$, where n is an arbitrary integer. Eq. (94) says that the magnetic monopole instantons of the compact $U(1)$ gauge theory are dual to charges of the dual phase field ϑ , which has a compact $U(1)$ global symmetry.

The full partition function is obtained by summing over all monopole configurations satisfying the total neutrality condition, $\sum_j m_j = 0$. As in section “Vortices in two dimensions,” we will weigh the configurations with a coupling u and find

$$Z = \sum_{\{m_j\}} Z\{m_j\} \int \mathcal{D}\vartheta \exp\left(-\frac{e^2}{2} \int d^3x (\partial_\mu \vartheta)^2 + \sum_j 2\pi i m_j \vartheta(x_j) - u \sum_j m_j^2\right) \quad (95)$$

which is the same theory we found in Eq. (77) except that now we are in 3D. Moreover, summing only over dilute configurations of monopoles and antimonopoles we find, once again the sine-Gordon theory but now in $D = 3$ dimensions:

$$Z = \int \mathcal{D}\vartheta \exp\left(-\int d^3x \left(\frac{e^2}{2} (\partial_\mu \vartheta)^2 - \nu \cos(2\pi\vartheta)\right)\right) \quad (96)$$

with $\nu = 2 \exp(-u)/a^3$.

In spite of the similarities between Eq. (96) and the sine-Gordon theory in 2D, Eq. (78), the physics is very different. It is straightforward to see that, in the limit $\nu = 0$, the monopole operator correlator is

$$\langle \exp(2\pi i \vartheta(x)) \exp(-2\pi i \vartheta(y)) \rangle = \exp\left(\frac{4\pi^2}{e^2} [G(|x-y|) - G(0)]\right) \simeq \exp\left(\frac{\pi}{2e^2} \left[\frac{1}{R} - \frac{1}{a}\right]\right) \quad (97)$$

where a is the short-distance cutoff. Unlike the behavior of the correlator of the vortex operators in 2D found in Eq. (79), Eq. (97) does not show a power-law behavior. The reason is that at $\nu = 0$ the compactified field ϑ should be regarded as the Goldstone boson of a spontaneously broken $U(1)$ symmetry. However, the cosine operator is now always relevant and the field ϑ is pinned and its fluctuations are actually massive.

Looking back at the partition function of Eq. (95), we could integrate out the field ϑ and obtain an expression with the same form as the Coulomb gas of Eq. (68) except that now this is the three-dimensional neutral Coulomb gas (Polyakov, 1977)

$$Z_{3DCG} = \sum_{\{m_j\}} \exp\left(-\frac{\pi}{2e^2} \sum_{j < k} m_j m_k \left[\frac{1}{|\mathbf{x}_j - \mathbf{x}_k|} - \frac{1}{a}\right]\right) \quad (98)$$

Now the energy of an isolated monopole is finite (in the infrared) while the entropy is still logarithmically divergent. The conclusion is that the monopoles proliferate and the 3D neutral Coulomb gas is always in a plasma phase with screened interactions. These results also imply that the expectation value of the Wilson loop operator in the $U(1)$ gauge theory decays exponentially with the *area* of the loop. The conclusion is that in 2+1 dimensions compact electrodynamics is in a confining phase for all values of the coupling constant e^2 (Polyakov, 1977, 1987).

Nonlinear sigma models and antiferromagnetic quantum spin chains

We will now discuss the one-dimensional case in which topology plays a crucial role. In one space dimension, the sites of the chain are labeled by an integer $j = 1, \dots, N$ (with N even). After some simple manipulations, the continuum limit of the staggered Wess–Zumino term of Eq. (52) is

$$\begin{aligned} \lim_{a_0 \rightarrow 0} S \sum_{j=1}^N (-1)^j \mathcal{S}_{WZ}[n(j, t)] &= \frac{S}{2} \int d^2x \mathbf{m}(x, t) \cdot \partial_t \mathbf{m}(x, t) \times \partial_x \mathbf{m}(x, t) \\ &+ S \int d^2x \mathbf{l}(x, t) \cdot \mathbf{m}(x, t) \times \partial_t \mathbf{m}(x, t) \end{aligned} \quad (99)$$

The continuum limit of the second term of Eq. (52) is essentially the same as in Eq. (55).

By putting together the results of Eqs. (99) and (55), we find that in the case of a 1D chain, the continuum field theory has the Lagrangian density

$$\mathcal{L}[\mathbf{m}, \mathbf{l}] = -2a_0 J S^2 \mathbf{l}^2 + S \mathbf{l} \cdot \mathbf{m} \times \partial_t \mathbf{m} - \frac{a_0 J S^2}{2} (\partial_x \mathbf{m})^2 + \frac{S}{2} \mathbf{m} \cdot \partial_t \mathbf{m} \times \partial_x \mathbf{m}. \quad (100)$$

Finally, we integrate out the ferromagnetic fluctuations represented by the massive field $\mathbf{l}(x, t)$ to find that the effective low-energy Lagrangian has the form

$$\mathcal{L} = \frac{1}{2g} \left(\frac{1}{v_s} (\partial_t \mathbf{m})^2 - v_s (\partial_x \mathbf{m})^2 \right) + \frac{\theta}{4\pi} \mathbf{m} \cdot \partial_x \mathbf{m} \times \partial_t \mathbf{m} \quad (101)$$

which is a nonlinear sigma model with $N = 3$ components (and hence has a global $O(3)$ symmetry) with a *topological term* whose coupling constant is θ . This result was first derived by Haldane (1985).

In Eq. (101), the effective coupling constant g , the spin-wave velocity v_s , and the θ -angle are given by $g = \frac{2}{S} v_s = 2a_0JS$, and $\theta = 2\pi$. As in the 2D case, since $g = 2/S$, large S implies that the nonlinear sigma model is in the weak coupling regime. Provided that $v_s > 0$, one can always rescale the time and space coordinates without affecting the form of the Lagrangian, including the coupling constant or, as we will see, the value of the θ angle. In what follows we will assume that we have done the rescaling in such a way that we set $v_s = 1$ and, that time and space scale as lengths. Thus we will use a relativistic notation and, after an analytic continuation to imaginary time, we label the time coordinate by x_2 and the space direction by x_1 . The partition function now takes the form

$$Z = \int \mathcal{D}\mathbf{m} \exp\left(-\frac{1}{2g} \int_{\Omega} d^2x (\partial_{\mu}\mathbf{n})^2 + i\theta Q[\mathbf{m}]\right) \quad (102)$$

where Ω is the spacetime manifold. In this notation, the first term of the exponent is called the Euclidean action of the nonlinear sigma model. In Eq. (102), we denoted by $Q[\mathbf{m}]$ the quantity

$$Q[\mathbf{m}] = \frac{1}{8\pi} \int_{\Omega} d^2x \epsilon_{\mu\nu} \mathbf{m} \cdot \partial_{\mu}\mathbf{m} \times \partial_{\nu}\mathbf{m} \quad (103)$$

Here we will consider the case in which the spacetime manifold Ω is closed. In particular we will assume that it is a two-sphere S_2 . The quantity $Q[\mathbf{m}]$ is the integral of a total derivative which counts the number of times the field configuration $\mathbf{m}(x_1, x_2)$ wraps around the sphere S_2 . In other words, it yields a nonvanishing result only for “large” configurations which wind (or wrap) around the sphere S_2 . Since $Q[\mathbf{n}]$ is an integer, it has the same for all *smooth* field configuration $\mathbf{m}$ that can be smoothly deformed into each other and are homotopically equivalent. If we demand that the field configurations $\mathbf{m}$ have finite Euclidean action, which requires that at infinity the configurations take the same (but arbitrary) value of $\mathbf{m}$, we have effectively compactified the $x_1 - x_2$ plane into a two sphere S_2 . On the other hand the field $\mathbf{m}$ is restricted by the constraint $\mathbf{m}^2 = 1$ to take values on a two-sphere S_2 . Therefore, the field configurations $\mathbf{m}(x_1, x_2)$ are smooth maps of the S_2 of the coordinate space to the S_2 of the target space of the field $\mathbf{m}$. Hence, the integer $Q[\mathbf{m}]$ classifies the smooth field configurations into a set of *equivalence classes* each labeled by the integer Q . Under composition homotopies form groups, and the equivalence classes themselves also form a group which, in this case, is isomorphic to the group of integers, $\mathbb{Z}$. In topology, these statements are summarized by the notation $\Pi_2(S_2) \simeq \mathbb{Z}$. The configurations with nonzero values of Q are called *instantons* which, in the quantum problem, represent tunneling processes of the nonlinear sigma model.

Another consequence of Q being an integer is that the contribution of its term to the weight of the path integral of Eq. (103) is a periodic function of θ angle. On the other hand, since the only allowed values of the θ are $\theta = 0 \pmod{2\pi}$ for S integer, or $\theta = \pi \pmod{2\pi}$ for S a half-integer, the contribution of the topological invariant Q to the weight of the path integral is

$$\exp(i\theta Q[\mathbf{m}]) = (-1)^{2SQ}. \quad (104)$$

Therefore, for spin chains with S integer, the weight is 1 and the topological invariant does not contribute to the path integral. But, if S is a half-integer, the weight is $(-1)^{Q[m]}$, and it does contribute. Moreover, its contribution is the same for all half-integer values of S .

These results have important consequences for the physics of spin chains which led Haldane to some startling conclusions (Haldane, 1985). In the weak coupling regime, $g \ll 1$ (equivalently, for large S), we can use the perturbative renormalization group and derive the beta function for all these $O(3)$ nonlinear sigma models (with or without topological terms) and find that their beta functions are the same as in Eq. (21) with $N = 3$. Hence, for all S , the effective coupling flows to large values. We can make this inference since the topological term yields no contribution for all configurations which are related by smooth deformations. Thus, we infer that all spin chains with S integer are in a massive phase with an exponentially small energy gap $\sim \exp(-2\pi S)$. This result is nowadays known as the Haldane gap.

On the other hand, these results also imply that all spin chain with half-integer spin S are also the same and, in particular, the same as spin-1/2 chains. However, the Hamiltonian of the quantum spin chain with spin-1/2 degrees of freedom is an example of an integrable system and its spectrum is known to be gapless from its Bethe Ansatz solution (Bethe, 1931; Yang and Yang, 1969). However, the spin-1/2 chain is not only gapless but its low energy states are gapless solitons with a relativistic spectrum. The low energy description of a theory of this type must be described by a conformal field theory. Haldane concluded that the RG flow for spin-1/2 chains must have an IR stable fixed point at some finite (and large) value of the coupling constant. This conjecture was confirmed by Affleck and Haldane (1987) who showed that the spin-1/2 Heisenberg chains are in the universality class of the $SU(2)_1$ Wess–Zumino–Witten model (Witten, 1984) whose CFT was solved by Knizhnik and Zamolodchikov (1984).

Topology and open integer-spin chains

In the preceding section, we showed that integer spin chains have a Haldane gap. We did that by showing that in that case the topological term is absent. However, the derivation is correct provided the spacetime manifold is closed, for example, a sphere and a torus. What happens if the system has a boundary? Let us denote the boundary of Ω by $\Gamma = \partial\Omega$. For example we will take Γ to be along the imaginary time direction and hence that it is a circle of circumference $1/T$, where T is the temperature. The topological term has the same form as the Berry phase term of the path integral for spin, the “Wess–Zumino” term of Eq. (44), but its prefactor is $1/2$ as big. Thus, for a system with an open boundary the topological term yields a net contribution equal to a Berry phase with a net prefactor of $S/2$.

In other words, the boundary of the integer spin chain behaves as a localized degree of freedom whose spin is $1/2$ (mod an integer). From the periodicity requirement, we also see that if the spin chain is made of *odd-integer* degrees of freedom, there should be a spin $1/2$ degree of freedom localized at the open boundary!. Conversely, if the chain is made of *even-integer* spins, there is no boundary degree of freedom! This line of argument implies that an antiferromagnetic chain with odd-integer spins must have a spin- $1/2$ degree of freedom at the boundary whereas a chain of even-integer spins should not. Notice that the “bulk” behavior is the same for both odd and even integer spin chains. The difference is whether or not they have a nontrivial “zero-mode” state at the boundary. In particular, the existence of this state is robust, that is, it cannot be removed by making smooth changes to the quantum Hamiltonian or, what is the same, the boundary state is *topologically protected*.

A simple system that displays a protected spin- $1/2$ zero mode at the boundary is a generalized $S = 1$ spin chain with Hamiltonian

$$H = \alpha \sum_{j=1}^N \mathbf{S}(j) \cdot \mathbf{S}(j+1) + \beta \sum_{j=1}^N (\mathbf{S}(j) \cdot \mathbf{S}(j+1))^2 \quad (105)$$

where $\mathbf{S}(j) = (S_x(j), S_y(j), S_z(j))$ are the spin 1 matrices at each lattice site j . This problem was examined in great detail by [Affleck et al. \(1988\)](#) who showed that at the special value of the parameters $\alpha = 1/2$ and $\beta = 1/6$ this Hamiltonian takes the form of a sum of projection operators

$$H = \sum_j P_2(\mathbf{S}(j) + \mathbf{S}(j+1)) \quad (106)$$

where P_2 is an operator that projects out the spin 2 states. These authors constructed the exact ground state, known as the AKLT state, of this Hamiltonian by writing each spin 1 degree of freedom of two spin- $1/2$ degrees of freedom at each site. They showed that the ground state is a projected product state in which the “constituent” spin- $1/2$ degrees of freedom (each labeled by $+$ and $-$, respectively) on nearby sites j and $j+1$ are in a valence bond singlet state of the form $\frac{1}{\sqrt{2}}(|\uparrow_{j,+} \downarrow_{j+1,-}\rangle - |\downarrow_{j,+} \uparrow_{j+1,-}\rangle)$ (and symmetrizing at each site to project onto a spin 1 state). This state of the spin-1 chain is translation invariant and gapped and hence agrees with Haldane’s result. Moreover, it has a spin- $1/2$ degree of freedom at each open boundary ([Hagiwara et al., 1990](#)).

The arguments discussed above show that the AKLT state is a gapped topological state. The gapless spin- $1/2$ boundary states are an example of *spin fractionalization*. The spin- $1/2$ boundary degrees of freedom are an example of an *edge state* which are present in many, though not all, topological phases of matter. One may ask what symmetry protects the gaplessness of these edge degrees of freedom. The only perturbation that would give a finite energy gap to the spin- $1/2$ edge states is an external magnetic field. However, this perturbation would break the global $SU(2)$ symmetry of the Hamiltonian as well as time-reversal invariance.

Duality in Ising models

Duality plays a significant role of our understanding of statistical physics and of quantum field theory. Many seemingly unrelated correspondences between different theories have come to be called *dualities*.

Duality in the 2D Ising model

One of the earliest versions of duality transformations was used to relate the high-temperature expansion of the 2D classical Ising model and its low-temperature expansion ([Kramers and Wannier, 1941](#)). In all dimensions, for concreteness, we will think of a hypercubic lattice, the high temperature expansion is a representation of the partition function as a sum of contributions of closed loops on the lattice. At temperature T , a configuration of loops γ contributes with a weight which in the Ising model has the form $C(\gamma) \tanh^{L(\gamma)}(\beta)$, where $\beta = 1/T$ and $L(\gamma)$ is the length of the loop γ , that is, the number of links on the loop, and $C(\gamma)$ is an entropic factor that counts the number of allowed loops with fixed perimeter $L(\gamma)$. However not all loop configurations are allowed as in the Ising model they satisfy constraints such as being nonoverlapping, etc.

In Section “The Ising model in a transverse field,” we noted that the partition function of the classical Ising model (in any dimension) can be interpreted as the path integral of a quantum spin model in one dimension less on a lattice with a discretized imaginary time. In this picture, the loops γ can be regarded as processes in which pairs of particles are created at some initial (imaginary) time, evolve and eventually are annihilated at a later (imaginary) time. In other words, the high-temperature phase is a theory of a massive scalar field. The restrictions on the allowed loop configurations represent interactions among these particles. In the temperature range in which the expansion in loops is convergent, the particles are massive as the loops are small. As the radius of convergence of the expansion is approached, longer and increasingly fractal-like loops begin to dominate the partition function, and concomitantly the mass of the particles decreases. This process is the signal of the approach to a continuous phase transition where the particles become massless. In fact, right at the critical point the particle interpretation is lost as the associated fields acquire anomalous dimensions.

Returning to the 2D classical Ising model, Kramers and Wannier also considered the low temperature expansion. This is an expansion around one of the broken symmetry state, for example, the state with all spins up. In this low temperature, regime the partition function is a sum of configurations of flipped spins. A typical configuration is a set of clusters of flipped spins.

In the absence of a uniform field, a configuration of flipped spins has a energy cost only on links of the lattice with oppositely aligned spins (“broken bonds”). Thus a cluster of flipped spins costs an energy equal to 2 (I assumed that I set $J = 1$) for each broken bond at the *boundary* of the cluster. This boundary is *domain wall*, which is a closed loop on the *dual lattice*. In 2D, the dual of the square lattice is the square lattice of the dual sites (the centers of the elementary plaquettes of the 2D lattice). In 2D, the links of the direct lattice pierce the links of the dual lattice. We can see that this analogous to the geometric duality of forms: sites (“0-forms”) are dual to plaquettes (“2-forms”) and links (“1-forms”) are dual to links (also “1-forms”).

Thus, in 2D the low temperature expansion is an expansion in the loops γ^* of the dual lattice that represent the domain walls. We can also regard the domain walls (the dual loops) as the histories the pairs of particles on the dual lattice. However, the weight of each dual loop is $\exp(-2\beta)$ per link of γ^* . Except for that, the counting and restrictions on the dual loops γ^* are the same as those of γ . This means that there is a one-to-one correspondence between the two expansions with the replacement $\tanh \beta \leftrightarrow \exp(-2\beta^*)$. This mapping means that the dual of the 2D classical Ising model (with global $\mathbb{Z}_2$ symmetry) at inverse temperature β is a dual Ising model (also with global $\mathbb{Z}_2$ symmetry) on the dual lattice at inverse temperature β^* . This correspondence is in close analogy with what we discussed in Section “Vortices in two dimensions.”

In particular if one assumes that there is a transition at $\beta_c = 1/T_c$ then there should also be a transition at $\beta_c^* = -1/2 \ln \tanh \beta_c$. Moreover, if one further assumes [as Kramers and Wannier did (Kramers and Wannier, 1941)] that there is a unique transition (correct in the Ising model but not in other cases), then the critical point must be such that $\exp(-2\beta_c) = \tanh \beta_c$, which yields the value $T_c = 2/\ln(\sqrt{2} + 1)$, which agrees with the Onsager’s result (Onsager, 1944).

In Section “The Ising model in a transverse field,” we showed that the classical 2D Ising model is equivalent to the one-dimensional Ising model in a transverse field whose Hamiltonian is given in Eq. (23). The 1D Ising model on a transverse field has spin degrees of freedom defined on the sites of a one-dimensional chain labeled by an integer-valued variable n . The 1D Hamiltonian is expressed in terms of local operators, the Pauli matrices $\sigma_3(n)$ and $\sigma_1(n)$. The 1D chain has a dual lattice whose sites are the midpoints of the chain. Thus in 1D, sites (“0-forms”) are dual to links (“1-forms”) and vice versa.

We will now see that there is a Hamiltonian version of the Kramers–Wannier duality (Fradkin and Susskind, 1978). In Eq. (26), we introduced the kink creation operator which flips are σ_3 operators to the left and including site j . For clarity we will denote the kink creation operator as $\tau_3(\tilde{n})$, where $\tilde{n}$ is the site of the dual lattice between the sites n and $n + 1$ of the original lattice. We will now define an operator $\tau_1(\tilde{n}) = \sigma_3(n)\sigma_3(n + 1)$. The operators $\tau_1(\tilde{n})$ and $\tau_3(\tilde{n})$ satisfy the same algebra of the Pauli operators $\sigma_1(n)$ and $\sigma_3(n)$. Furthermore, we readily find the Hamiltonian of the dual theory to be the same (up to boundary conditions) as the original Hamiltonian of Eq. (23) except that the dual coupling constant is $\lambda^* = 1/\lambda$. So, once again, if we assume that there is a single (quantum) phase transition we require $\lambda_c^* = \lambda_c$, which is only satisfied by $\lambda_c = 1$. In this language, the kink creation operator plays the role of a disorder operator (Fradkin and Susskind, 1978).

The 3D duality: $\mathbb{Z}_2$ gauge theory

We will now discuss the role of duality in the 3D Ising model on a cubic lattice. This case, and its generalizations to higher dimensions, was considered first by Wegner (1971).

In Section “Duality in the 2D Ising model,” we discussed the loop representation of the high temperature expansion and showed that it has the form in all dimensions. Hence, in 3D the high temperature expansion is an expansion in closed loops γ with weight of $\tanh \beta$ per unit link of loop. Hence, in 3D as well, the high temperature phase can be regarded as field theory of a massive scalar field. As in the 2D case, the weight of a loop configuration is $\tanh \beta$ for each link of the loop γ .

However, the low temperature expansion has a radically different form and physical interpretation. Much as in 2D, the low temperature expansion is an expansion in clusters of flipped spins. Here too, in the absence of an external field, the only energy cost resides at the boundary of the clusters of overturned spins, the domain walls. But in 3D, the clusters occupy volumes whose boundaries are closed *surfaces* Σ^* . In 3D a link (bond) is dual to a plaquette (expressing the fact that in 3D a 1-form is dual to a 2-form). Hence the closed domain walls of overturned spins are dual to a closed surface Σ^* on the dual lattice. The weight of each configuration of closed surfaces is $\exp(-2\beta)$ for each plaquette of the surface Σ^* .

These facts mean that the dual theory of the 3D Ising model is a theory on the dual lattice with coupling constant β^* , with $\exp(-2\beta^*) = \tanh \beta$, such that its expansion for small β^* is a sum over configurations of closed surfaces σ^* , and for large β^* is a sum of configurations of closed loops γ^* on the dual lattice. The dual theory is the naturally defined on (dual) plaquettes, not on links. To this end, let us define a set of Ising-like degrees of freedom $\sigma_\mu(x) = \pm 1$ located on the links (x, μ) of the dual lattice. These degrees of freedom are coupled on each plaquette of the lattice. Since each plaquette has four links, the coupling involves the degrees of freedom on all four links of each plaquette. The partition function of the dual theory is

$$Z = \sum_{\{\sigma_\mu(x)\}} \exp \left(\beta^* \sum_{\text{plaquettes}} \sigma_\mu(x) \sigma_\nu(x + e_\mu) \sigma_\mu(x + e_\mu + e_\nu) \sigma_\nu(x) \right) \quad (107)$$

where the sum in the exponent (the negative of the “action”) runs on all the plaquettes of the dual lattice.

The action of the theory of Eq. (107) is invariant under the reversal of all six Ising degrees of freedom on links sharing a given site x . This is a *local symmetry*. Unlike the 3D Ising model, which has a global $\mathbb{Z}_2$ symmetry of flipping all spins simultaneously, this theory has *local* (or *gauge*) $\mathbb{Z}_2$ symmetry. This is the simplest example of a lattice gauge theory in which the degrees of freedom are gauge fields that take values on the $\mathbb{Z}_2$ gauge group (Wegner, 1971; Wilson, 1975; Kogut, 1979).

We saw that in the spin model the high temperature expansion (i.e., the expansion in powers of $\tanh \beta$) is a sum over loop configurations which can be interpreted in terms of processes in which pairs of particles are created, evolve (in imaginary time), and then are destroyed (also in pairs). The analogous interpretation of the expansion of the $\mathbb{Z}_2$ gauge theory in powers of $\tanh \beta^* = \exp(-2\beta)$ as a sum over the configurations of closed surfaces is not in terms of the histories of *particles* but in terms of the histories of closed strings which, as they evolve, sweep the closed surfaces. The physics is, however, more complex as the sum over surfaces runs over all surfaces of arbitrary topology with arbitrary number of handles (or *genus*). Thus, over (imaginary) time a closed strong is created, evolves, splits into two closed strings, etc.

Therefore, the 3D Ising model, which has a $\mathbb{Z}_2$ global symmetry, is dual to a $\mathbb{Z}_2$ gauge theory, which has a $\mathbb{Z}_2$ local symmetry. The duality maps the high temperature (disordered) phase of the Ising model to the strong coupling (small β^*) phase of the gauge theory. In the gauge theory language, this is the *confining* phase. This can be seen by computing the expectation value of the Wilson loop operator on the closed loop Γ , which here reads $\langle \prod_{(x,\mu) \in \Gamma} \sigma_\mu(x) \rangle$. In the small β^* phase, this expectation value decays exponentially with the size of the minimal surface bounded by the loop Γ . This behavior of the area law of the Wilson loop. Under duality, the insertion of this operator is equivalent to an Ising model with a domain wall terminating on the loop Γ , and the area law of the Wilson loop is the consequence of the fact that if the Ising model has long-range order, the free energy cost of the domain wall scales with its area. Moreover, in this phase of the gauge theory, the closed strings are small meaning that the string tension (the energy per unit length of string) is finite. In the Ising model language, the string tension becomes surface tension of the domain wall.

In the preceding section, we discussed a Hamiltonian version of the duality. We will briefly do the same in the case of the 2+1 dimensional Ising model. The Hamiltonian of the Ising model in a transverse field on a square lattice is

$$H_{2D-TFIM} = -\sum_{\mathbf{r}} \sigma_1(\mathbf{r}) - \lambda \sum_{\mathbf{r}, j=1,2} \sigma_3(\mathbf{r}) \sigma_3(\mathbf{r} + \mathbf{e}_j) \quad (108)$$

where $\mathbf{r}$ labels the sites of the square lattice and $\mathbf{e}_j$ (with $j = 1, 2$) are the two (orthonormal) primitive unit vectors of the lattice. Here too, at each site we have a two-level system (the spins), σ_1 and σ_3 are Pauli matrices acting on these states at each site and λ is the coupling constant. Just as in the 1D case, this system has two phases: an ordered phase for $\lambda > \lambda_c$ and a disordered phase for $\lambda < \lambda_c$, where λ_c is a critical coupling. This Hamiltonian is invariant under the global $\mathbb{Z}_2$ symmetry generated by the global spin flip operator $Q = \prod_{\mathbf{r}} \sigma_1(\mathbf{r})$ which commutes with the Hamiltonian, $[Q, H_{2D-TFIM}] = 0$.

Let us consider now a $\mathbb{Z}_2$ gauge theory on the dual of the square lattice. We will now define a two-dimensional Hilbert space on each link, denoted by $(\tilde{\mathbf{r}}, j)$ (with $j = 1, 2$) of the dual lattice with sites labeled by $\tilde{\mathbf{r}}$. We will further define at each link $(\tilde{\mathbf{r}}, j)$ the Pauli operators $\sigma_j^1(\tilde{\mathbf{r}})$ and $\sigma_j^3(\tilde{\mathbf{r}})$. The Hamiltonian of the $\mathbb{Z}_2$ gauge theory is

$$H_{\mathbb{Z}_2 \text{ gauge}} = -\sum_{\tilde{\mathbf{r}}, j} \sigma_j^1(\tilde{\mathbf{r}}) - g \sum_{\tilde{\mathbf{r}}} \sigma_1^3(\tilde{\mathbf{r}}) \sigma_2^3(\tilde{\mathbf{r}} + \tilde{\mathbf{e}}_1) \sigma_1^3(\tilde{\mathbf{r}} + \tilde{\mathbf{e}}_1 + \tilde{\mathbf{e}}_2) \sigma_2^3(\tilde{\mathbf{r}} + \tilde{\mathbf{e}}_2) \quad (109)$$

where $\tilde{\mathbf{e}}_j = \epsilon_{jk} \mathbf{e}_k$ (with $j, k = 1, 2$).

Unlike the Hamiltonian of Eq. (108), the Hamiltonian of Eq. (109) has a local symmetry. Let $\tilde{Q}(\tilde{\mathbf{r}})$ be the operator that flips the $\mathbb{Z}_2$ gauge degrees of freedom on the four links that share the site $\tilde{\mathbf{r}}$,

$$\tilde{Q}(\tilde{\mathbf{r}}) = \prod_{j=1,2} \sigma_j^1(\tilde{\mathbf{r}}) \sigma_j^1(\tilde{\mathbf{r}} - \tilde{\mathbf{e}}_j) \quad (110)$$

These operators commute with each other, $[\tilde{Q}(\tilde{\mathbf{r}}), \tilde{Q}(\tilde{\mathbf{r}}')] = 0$, and commute with the Hamiltonian, $[H_{\mathbb{Z}_2 \text{ gauge}}, \tilde{Q}(\tilde{\mathbf{r}})] = 0$. The Hilbert space of gauge-invariant states is eigenstates of $\tilde{Q}(\tilde{\mathbf{r}})$ with unit eigenvalue,

$$\tilde{Q}(\tilde{\mathbf{r}})|\text{Phys}\rangle = |\text{Phys}\rangle \quad (111)$$

(for all $\tilde{\mathbf{r}}$). This constraint is the $\mathbb{Z}_2$ Gauss Law. The Hamiltonian $H_{\mathbb{Z}_2 \text{ gauge}}$ has two phases: a *confining* phase for $g < g_c$ and a *deconfined* phase for $g > g_c$ (where g_c is a critical coupling).

The duality transformation is defined so that

$$\sigma_1(\mathbf{r}) = \prod_{\text{plaquette}(\mathbf{r})} \sigma_j^3(\tilde{\mathbf{r}}) \quad (112)$$

is the product of the σ_j^3 operators of the gauge theory on a dual plaquette centered at the site $\mathbf{r}$, and

$$\sigma_1^1(\tilde{\mathbf{r}}) = \sigma_3(\mathbf{r}) \sigma_3(\mathbf{r} + \mathbf{e}_2), \quad \sigma_2^1(\tilde{\mathbf{r}}) = \sigma_3(\mathbf{r}) \sigma_3(\mathbf{r} + \mathbf{e}_1) \quad (113)$$

These identities imply that the gauge theory constraint of the $\mathbb{Z}_2$ Gauss Law, Eq. (111), is satisfied. This also means that duality is a mapping of the *gauge-invariant* sector of the $\mathbb{Z}_2$ gauge theory to the Hilbert space of the Ising model in a transverse field.

Eqs. (112) and (113) imply that the Hamiltonians $H_{2D-TFIM}$ and $H_{\mathbb{Z}_2 \text{ gauge}}$ are equal to each other with the identification of the coupling constants $g = 1/\lambda$. Hence, the *ordered phase* of the Ising model, $\lambda > \lambda_c$, maps onto the *confining phase* of the $\mathbb{Z}_2$ gauge theory and, conversely, the *disordered phase* of the Ising model maps onto the *deconfined phase* of the gauge theory.

Eq. (113) also implies that the operator $\sigma_3(\mathbf{r})$ of the Ising model can be identified with the operator

$$\sigma_3(\mathbf{r}) = \prod_{\gamma(\mathbf{r})} \sigma_j^1(\tilde{\mathbf{r}}) \quad (114)$$

where the product is on the links of the dual lattice pierced by the path $\gamma(\mathbf{r})$ on the direct lattice ending at the site $\mathbf{r}$.

While $\sigma_3(\mathbf{r})$ is of course just the order parameter of the Ising model, the dual operator defined by Eq. (114) anticommutes with the plaquette term of the Hamiltonian of Eq. (109) and creates an $\mathbb{Z}_2$ flux excitation at the plaquette. With some abuse of language, this operator can be regarded as creating a $\mathbb{Z}_2$ “magnetic monopole.” Since in the confining phase this operator has an expectation value, we can regard this phase as a magnetic condensate.

We will now discuss the role of boundary conditions, which is different in both theories. Let us examine the behavior of the $\mathbb{Z}_2$ gauge theory with periodic boundary conditions. Periodic boundary conditions means that the 2D space is topologically a 2-torus. It is straightforward to show that the ground state in the confining phase is unique and insensitive to boundary conditions. The physics of the deconfined phase is more subtle. We will now see that on a 2-torus it has a fourfold degenerate ground state and that the degeneracy is not due to the spontaneous breaking of a global symmetry.

Let γ_1 and γ_2 be two noncontractible loops on the torus along the directions 1 and 2, respectively. Let us consider the (“electric”) Wilson loop operators along γ_1 and γ_2 , $W[\gamma_1] = \prod_{(r,j) \in \gamma_1} \sigma_j^3(\mathbf{r})$ and similarly for γ_2 . Similarly let us consider the (“magnetic”) ’t Hooft operators $\tilde{W}[\tilde{\gamma}_1]$ and $\tilde{W}[\tilde{\gamma}_2]$ defined on the noncontractible closed paths of the dual lattice $\tilde{\gamma}_1$ and $\tilde{\gamma}_2$, such that $\tilde{W}[\tilde{\gamma}_1] = \prod_{\tilde{\gamma}_1} \sigma_2^1(\tilde{\mathbf{r}})$ and $\tilde{W}[\tilde{\gamma}_2] = \prod_{\tilde{\gamma}_2} \sigma_1^1(\tilde{\mathbf{r}})$. It is easy to see that the Wilson and ’t Hooft operators satisfy that $W[\gamma_i]^2 = \tilde{W}[\tilde{\gamma}_j]^2 = I$, and that

$$[W[\gamma_i], W[\gamma_j]] = [\tilde{W}[\tilde{\gamma}_i], \tilde{W}[\tilde{\gamma}_j]] = 0, \quad \{W[\gamma_1], \tilde{W}[\tilde{\gamma}_2]\} = \{W[\gamma_2], \tilde{W}[\tilde{\gamma}_1]\} = 0 \quad (115)$$

Let us consider the special limit of $g \rightarrow \infty$. In this limit the Wilson loop operators $W[\gamma_i]$ on the two noncontractible loops of the 2-torus commute with the Hamiltonian $H_{\mathbb{Z}_2 \text{ gauge}}$ of Eq. (109). Therefore the eigenstates of the Hamiltonian can be chosen to be the eigenstates of these two Wilson loops. Since the Wilson loop operators are Hermitian and obey $W[\gamma_i]^2 = I$, the spectrum of each loop is two-dimensional $|\pm 1\rangle_i$ ($i = 1, 2$) with eigenvalues ± 1 , respectively. At $g \rightarrow \infty$, these states are also eigenstates of $H_{\mathbb{Z}_2 \text{ gauge}}$. Thus, the ground state of $H_{\mathbb{Z}_2 \text{ gauge}}$ is four dimensional. The ’t Hooft loops $\tilde{W}[\tilde{\gamma}_i]$ act as ladder operators in this restricted Hilbert space.

The conclusion is that, on a 2-torus, at least in the limit $g \rightarrow \infty$, the ground state of $H_{\mathbb{Z}_2 \text{ gauge}}$ is degenerate. However, this degeneracy is not due to the spontaneous breaking of a global symmetry. Rather, it reflects the topological character of the theory. To see this, one can extend this analysis to a theory to be on a more general two-dimensional and instead of a 2-torus we can consider a surface with g handles (not to be confused with the coupling constant!), for example, $g = 0$ for a sphere (or disk), $g = 1$ for a 2-torus, $g = 2$ for a pretzel, etc. For each of these two-dimensional surfaces, the different number of noncontractible loops is g , and the Wilson loops defined on them commute with each other (and with $H_{\mathbb{Z}_2 \text{ gauge}}$). Hence, in the limit $g \rightarrow \infty$, $H_{\mathbb{Z}_2 \text{ gauge}}$ has a ground state degeneracy of 2^g which, clearly, depends only on the topology of the surface. We conclude that, at least as $g \rightarrow \infty$, the Hamiltonian $H_{\mathbb{Z}_2 \text{ gauge}}$ is in a *topological phase*.

However, is the exact degeneracy found in the limit $g \rightarrow \infty$ a property of the entire deconfined phase? For a finite system, the expansion in powers of $1/g$ is convergent. On the other hand, in the thermodynamic limit, $L \rightarrow \infty$, the expansion has a finite radius of convergence with g_c being an upper bound. Let us consider the ground state at $g = \infty$ with eigenvalue $+1$ for the Wilson loop $W[\gamma_1]$. The degenerate state with eigenvalue -1 is created by the ’t Hooft loop $\tilde{W}[\tilde{\gamma}_2]$, that is, $|-1\rangle_1 = \tilde{W}[\tilde{\gamma}_2] | +1\rangle_1$. The ’t Hooft operator is a product of σ^1 operators on links along the direction 1 crossed by the path $\tilde{\gamma}_2$ of the dual lattice, which involves (at least) L links. Then, it takes L orders in the expansion in powers of $1/g$ to mix the state $| +1\rangle_1$ with the state $| -1\rangle_1$, and this amplitude is of order $1/g^L$, which is exponentially small. The same argument applies to the mixing between all four states. For a finite but large system of linear size L , the degeneracy is lifted but the energy splitting is exponentially small in the system size. Hence, the topological protection is a feature of the deconfined phase in the thermodynamic limit $L \rightarrow \infty$.

We conclude that the deconfined phase of the $\mathbb{Z}_2$ lattice gauge theory is a topological phase. This result extends to the case of a gauge theory with discrete gauge group $\mathbb{Z}$, the cyclic group of k elements. In general spacetime dimension $D > 2$, the $\mathbb{Z}_k$ gauge theory also has confined and deconfined phases and if $k \geq 4$, it also has an intermediate “Coulomb phase” (Elitzur et al., 1979; Ukawa et al., 1980). In Section “BF gauge theory,” we will see that the low-energy (IR) regime of the deconfined phase is described by a topological quantum field theory known as the level k BF theory.

Bosonization

The behavior of one-dimensional electronic systems is of great interest in condensed matter physics for many reasons. One is that, even for infinitesimally weak interactions, these one-dimensional metals violate the basic principles of the Landau Theory of the FL (Baym and Pethick, 1991). A central assumption of Fermi Liquid theory is that at low energies the excitation energy of the fermion (electron) quasiparticle is always much larger than its width. Hence, at asymptotically low energies, the quasiparticle excitations become increasingly sharp.

A manifestation of this feature is that the quasiparticle propagator (the “Green function”) has a pole on the real frequency axis with a finite residue Z . In one-dimensional metals, this assumption always fails since the residue Z vanishes, the Fermi field acquires a nontrivial anomalous dimension, and the pole is replaced by a branch cut. To this date this is the best example of what is called a

“non-Fermi liquid.” In one-dimensional metals, this non-Fermi liquid is often called a “Luttinger Liquid” (Haldane, 1981). A detailed analysis can be found in Chapter 6 of Fradkin (2013), and in other books.

Bosonization provides for a powerful tool to understand the physics of these nontrivial systems. Bosonization is a duality between a massless Dirac field in 1+1 dimensions and a (also massless) relativistic Bose (scalar) field (Mattis and Lieb, 1965; Luther and Emery, 1974; Mandelstam, 1975; Coleman, 1975). In this context, bosonization is a set of operator identities relating observables between two different (dual) continuum field theories. These identities have a close resemblance to the Jordan–Wigner transformation, which relates operators of a theory of spinless (Dirac) fermions on a one-dimensional lattice to a theory of bosons with hard cores (i.e., spins) on the same lattice (Lieb et al., 1961).

Dirac fermions in one space dimensions

To understand how these operator identities come about and what these fields mean in the Condensed Matter, context we will consider the simple problem of a system of noninteracting spinless fermions $c(n)$ on a one-dimensional chain of length L (with $L \rightarrow \infty$) for simplicity with periodic boundary conditions. The Hamiltonian is

$$H_0 = -t \sum_{n=1}^L c(n)^\dagger c(n+1) + \text{h.c.} \quad (116)$$

In momentum space, and in the thermodynamic limit $L \rightarrow \infty$, the Hamiltonian becomes

$$H_0 = \int_{-\pi}^{\pi} \frac{dp}{2\pi} (\varepsilon_0(p) - \mu) c^\dagger(p) c(p) \quad (117)$$

where $-\pi \leq p \leq \pi$, μ is the chemical potential (which fixes the fermion number) and $\varepsilon_0(p)$ is the (free) quasiparticle energy which, in this case, is

$$\varepsilon_0(p) = -2t \cos p. \quad (118)$$

This simple system has a global internal symmetry

$$c'(n) = e^{i\alpha} c(n), \quad c'(n)^\dagger = e^{-i\alpha} c(n)^\dagger \quad (119)$$

where α is a constant phase (with period 2π). This global symmetry reflects the conservation of fermion number

$$N_F = \sum_n c^\dagger(n) c(n). \quad (120)$$

The free fermion Hamiltonian of Eq. (116) is also invariant under lattice translations.

The ground state of this system is obtained by occupying all single particle states with energy below the chemical potential, $E \leq \mu \equiv EF$, which defines the Fermi energy E_F . In what follows we will redefine the zero of the energy at the Fermi energy. In the thermodynamic limit, the one-particle states are labeled by momenta defined in the first Brillouin zone $[-\pi, \pi)$. The ground state $|G\rangle$ of this system is obtained by filling up all single-particle states with momentum p in the range $[-p_F, p_F]$, where p_F is the Fermi momentum. Hence, the occupied states have energy $\varepsilon_0(p) \leq E_F$. The ground state is

$$|G\rangle = \prod_{|p| \leq p_F} c^\dagger(p) |0\rangle \quad (121)$$

and is called the *filled Fermi sea*. We will further assume that the fermionic system is dense in the sense that the occupied states are a finite fraction of the available states, that is, we assume that $|E_F|$ is a *finite* fraction of the bandwidth $W = 4t$.

The single-particle excitations have low energy if $|\varepsilon_0(p) - E_F| \ll |E_F|$. This range can only be accessed by quasiparticles with momenta p close to $\pm p_F$. For states with p close to p_F , we can a linearized approximation and write

$$\varepsilon_0(p) \simeq v_F(p - p_F) + \dots \quad (122)$$

and similarly for the states near $-p_F$. Here $v_F = \left. \frac{\partial \varepsilon_0}{\partial p} \right|_{p_F} = 2t \sin p_F$ is the Fermi velocity. Let q being the momentum measured from p_F (or $-p_F$ in the other case), this approximation is correct in a range of momenta $-\Lambda \leq q \leq \Lambda$, where $\frac{2\pi}{L} \ll \Lambda \ll \pi$. In this regime we can approximate the lattice fields $c(n)$ with two continuum right moving $\psi_R(x)$ and left moving $\psi_L(x)$ Fermi fields such that (with $x = na_0$)

$$c(n) \sim e^{ip_F x} \psi_R(x) + e^{-ip_F x} \psi_L(x) \quad (123)$$

in terms of which the Hamiltonian takes the continuum form

$$\begin{aligned} H_{\text{continuum}} &= \int dx \left(\psi_R^\dagger(x) (-iv_F) \partial_x \psi_R(x) - \psi_L^\dagger(x) (-iv_F) \partial_x \psi_L(x) \right) \\ &= \int \frac{dq}{2\pi} q v_F \left(\psi_R^\dagger(q) \psi_R(q) + \psi_L^\dagger(q) \psi_L(q) \right). \end{aligned} \quad (124)$$

In what follows I will rescale time and space in such a way as to set $v_F = 1$.

Eq. (124) is the Hamiltonian of a massless Dirac field in 1+1 dimensions. It describes the effective low energy behavior of the excitations of the fermionic system defined on a lattice by the Hamiltonian of Eq. (116). Here low energy means asymptotically close to the Fermi energy (which we have set to zero) and momenta close to $\pm p_F$. We will see that this effective relativistic field theory gives a complete description of the universal low energy physics encoded in the microscopic model of Eq. (116) up to some subtle issues associated with what are called quantum anomalies.

Let us denote by $\psi(x)$ the bi-spinor field $\psi(x) = (\psi_R(x), \psi_L(x))$ and the 2×2 Dirac gamma-matrices in terms of the three Pauli matrices are

$$\gamma_0 = \sigma_1, \quad \gamma_1 = -i\sigma_2, \quad \gamma_5 = \sigma_3 \quad (125)$$

which obey the Dirac algebra

$$\{\gamma_\mu, \gamma_\nu\} = 2g_{\mu\nu} \quad (126)$$

where $g_{\mu\nu}$ is the metric tensor in 1+1-dimensional Minkowski spacetime

$$g_{\mu\nu} = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}. \quad (127)$$

Using the standard notation $\bar{\psi}(x) = \psi^\dagger(x)\gamma_0$ (where I left the spinor index $\alpha = 1, 2$ implicit), the Lagrangian density of the free massless Dirac fermion is

$$\mathcal{L} = \bar{\psi} i \not{\partial} \psi \quad (128)$$

where we have used the Feynman slash notation, which denotes the contraction of a vector field, say A_μ with the Dirac gamma matrices with a slash, $A_\mu \gamma^\mu \equiv \not{A}$.

Formally, the Dirac Lagrangian of Eq. (128) (and the Dirac Hamiltonian of Eq. (124)) is invariant under two separate global transformations. It has a global $U(1)$ (gauge) symmetry transformation

$$\psi'(x) = e^{i\theta} \psi(x) \quad (129)$$

(where θ is constant) under which the two components of the bi-spinor ψ transform in the same way

$$\psi'_R(x) = e^{i\theta} \psi_R(x), \quad \psi'_L(x) = e^{i\theta} \psi_L(x). \quad (130)$$

The massless Dirac theory is also invariant under a global gauge $U(1)$ chiral transformation

$$\psi'(x) = e^{i\theta\gamma_5} \psi(x) \quad (131)$$

which in components reads

$$\psi'_R(x) = e^{i\theta} \psi_R(x), \quad \psi'_L(x) = e^{-i\theta} \psi_L(x). \quad (132)$$

In general, if a system has a global continuous symmetry, it should have a locally conserved current and a globally conserved charge. This is the content of Noether's Theorem. Since the massless Dirac theory has these two global symmetries, one would expect that it should have two separately conserved currents.

The global $U(1)$ symmetry has an associated current $j_\mu = (j_0, j_1)$ given by

$$j_\mu = \bar{\psi} \gamma_\mu \psi \quad (133)$$

which is invariant under the global $U(1)$ symmetry. In terms of the right and left moving Dirac fields, ψ_R and ψ_L , the components of the current are

$$j_0 = \psi_R^\dagger \psi_R + \psi_L^\dagger \psi_L, \quad j_1 = \psi_R^\dagger \psi_R - \psi_L^\dagger \psi_L. \quad (134)$$

This current is locally conserved and satisfies the continuity equation

$$\partial_\mu j^\mu = 0. \quad (135)$$

It has an associated conserved global charge, which we will call fermion number

$$Q = \int_{-\infty}^{\infty} dx j_0(x) = \int_{-\infty}^{\infty} dx (\psi_R^\dagger \psi_R + \psi_L^\dagger \psi_L). \quad (136)$$

This is the continuum version of the conservation of fermion number N_F of the free fermion lattice model discussed above.

Since this current is conserved, it can be coupled to an electromagnetic field through a term in the Lagrangian

$$\mathcal{L}_{\text{int}} = -e j_\mu A^\mu \quad (137)$$

where A^μ is the electromagnetic vector potential, which in 1+1 dimensions has only two components, $A^\mu = (A_0, A_1)$. Here, e is a coupling constant, which is interpreted as the electric charge. This coupling amounts to making the $U(1)$ symmetry a local gauge symmetry under which the fields transform as

$$\psi'(x) = e^{i\theta(x)}\psi(x), \quad A'_\mu(x) = A_\mu(x) + \frac{1}{e}\partial_\mu\theta(x). \quad (138)$$

Now the conservation of fermion number becomes the conservation of the total electric charge

$$Q_e = -eQ. \quad (139)$$

In a continuum nonrelativistic model, the Fermi field is $\psi(x)$ (ignoring spin), for example, an electron gas in one dimension such as a quantum wire, the analog of decomposition shown in Eq. (123) of the electron field $\psi(x)$ becomes

$$\psi(x) = e^{ip_F x}\psi_R(x) + e^{-ip_F x}\psi_L(x). \quad (140)$$

The electron field $\psi(x)$ transforms as $\psi'(x) = e^{ix}\psi(x)$ under the global $U(1)$ gauge symmetry of Eq. (130). In particular, the local density operator $\rho(x) = \psi^\dagger(x)\psi(x)$ is invariant under this symmetry. Under both decompositions of Eqs. (123) and (140), the local density operator becomes

$$\rho(x) = \psi_R^\dagger(x)\psi_R(x) + \psi_L^\dagger(x)\psi_L(x) + e^{i2p_F x}\psi_R^\dagger(x)\psi_L(x) + e^{-i2p_F x}\psi_L^\dagger(x)\psi_R(x) \quad (141)$$

Clearly the nonrelativistic density operator $\rho(x)$ is invariant under the global $U(1)$ gauge symmetry. The same considerations apply to the lattice version of the density operator (the local occupation number).

Thus, the density operator $\rho(x)$ can be decomposed into a slowly varying part (the first two terms in Eq. (141)) and the last two terms which oscillate with wave vectors $Q = \pm 2p_F$. These observations imply that we can express $\rho(x)$ in the form

$$\rho(x) = \bar{\rho} + j_0(x) + e^{iQx}\psi_Q(x) + e^{-iQx}\psi_{-Q}(x). \quad (142)$$

This decomposition can be interpreted as a Fourier expansion of the density operator in term of newly defined slowly varying fields. In Eq. (142), $Q = 2p_F$ and $\bar{\rho}$ is the average density, where we assumed that the Dirac density operator $j_0(x)$ has vanishing expectation value (i.e., it is normal-ordered). In Eq. (142), we defined the (bosonic) operators

$$\psi_Q(x) = \psi_R^\dagger(x)\psi_L(x), \quad \psi_{-Q}(x) = \psi_L^\dagger(x)\psi_R(x) \quad (143)$$

which characterize the oscillatory component of the density. The operators $\psi_{\pm Q}(x)$ are the order parameters of a charge density wave state in one dimension and Q is the ordering wavevector.

Repulsive interactions between the electrons can cause scattering process between the right and left moving components to become relevant (in the Renormalization Group sense) leading to the spontaneous breaking of translation invariance. The resulting state is known as a charge-density-wave (CDW). In this state the operators $\psi_{\pm Q}(x)$ (or a linear combination of them) acquire a nonvanishing expectation value, and the expectation value of the density operator $\rho(x)$ has a (static) modulated component, and the Dirac Hamiltonian density becomes

$$\mathcal{H} = \psi_R^\dagger(x)(-i)\partial_x\psi_R(x) - \psi_L^\dagger(x)(-i)\partial_x\psi_L(x) + m(\psi_R^\dagger(x)\psi_L(x) + \psi_L^\dagger(x)\psi_R(x)) \quad (144)$$

where m is the Dirac mass. The operator in the second term of Eq. (144) mixes the right and left moving components of the Dirac spinor. This Hermitian operator is known as the Dirac mass term. In relativistic notation this operator is written as

$$\bar{\psi}\psi = \psi_R^\dagger(x)\psi_L(x) + \psi_L^\dagger(x)\psi_R(x). \quad (145)$$

When $m \neq 0$, that is, when $\langle\bar{\psi}\psi\rangle \neq 0$, the fermionic spectrum has a mass gap, and the electronic states with momenta $\pm p_F$ have an energy gap. Alternatively we could have considered a state with the in which the (Hermitian) operator that has an expectation value is

$$i\bar{\psi}\gamma_5\psi = i(\psi_R^\dagger(x)\psi_L(x) - \psi_L^\dagger(x)\psi_R(x)) \quad (146)$$

which is known as the γ_5 mass term. In a more general CDW state both mass terms can be present.

Chiral symmetry and chiral symmetry breaking

The CDW states we introduced have different symmetries. To see this let us observe that the operators $\psi_{\pm Q}(x)$ transform nontrivially under a global $U(1)$ chiral transformation

$$\psi'_{\pm Q}(x) = e^{\mp 2i\theta}\psi_{\pm Q}(x). \quad (147)$$

Upon substituting this transformation in the expansion of the density $\rho(x)$ of Eq. (142), we see that a chiral transformation is equivalent to a uniform displacement of the density operator by θ/p_F ,

$$\rho(x) \rightarrow \rho(x + \theta/p_F). \quad (148)$$

Under a chiral transformation with arbitrary angle θ , the Dirac and γ_5 mass term operators transform as an orthogonal transformation of a two-component vector. In particular for a chiral transformation with $\theta = \pi/4$,

$$\bar{\psi}\psi \mapsto i\bar{\psi}\gamma_5\psi, \quad i\bar{\psi}\gamma_5\psi \mapsto -\bar{\psi}\psi \quad (149)$$

which is equivalent to a displacement of the density by $1/4$ of the period of the CDW. In this sense these two states are equivalent, as is the state with a more general linear combination.

The microscopic lattice model (and the continuum nonrelativistic model) is invariant under the spatial inversion symmetry $x \leftrightarrow -x$. This also implies a symmetry under the exchange of right and left moving components of the Dirac spinor, $\psi_R \leftrightarrow \psi_L$. In the massless Dirac theory this operation is equivalent to the multiplication of the spinor by the Pauli matrix σ_1 . In the massless theory, the multiplication by σ_2 (followed by a chiral transformation with $\theta = \pi/2$) has the same effect.

These symmetries have an important effect on the fermionic spectrum. To understand what they do let us consider the one-particle Dirac Hamiltonian with a Dirac mass m (in momentum space)

$$h = \begin{pmatrix} p & m \\ m & -p \end{pmatrix}. \quad (150)$$

This operator anticommutes with the Pauli matrix σ_2 , $\{h, \sigma_2\} = 0$. Let $|E\rangle$ be an eigenstate of the Hamiltonian h with energy eigenvalue $E = \sqrt{p^2 + m^2}$. Let us consider the state $\sigma_2|E\rangle$. It is also an eigenstate of h but with energy $-E$, that is,

$$h\sigma_2|E\rangle = -\sigma_2h|E\rangle = -E|E\rangle, \quad \Rightarrow \sigma_2|E\rangle = |-E\rangle. \quad (151)$$

Hence if $|E\rangle$ is an eigenstate of energy E , then $\sigma_2|E\rangle$ is an eigenstate of energy $-E$. This means that the spectrum is invariant under charge conjugation symmetry. Notice that under this operation the spinor transforms as

$$\sigma_2 \begin{pmatrix} \psi_R \\ \psi_L \end{pmatrix} = \begin{pmatrix} -i\psi_L \\ i\psi_R \end{pmatrix} = e^{-i\gamma_5\pi/2} \begin{pmatrix} \psi_L \\ \psi_R \end{pmatrix}. \quad (152)$$

In other words, this theory is invariant under charge conjugation C and parity $\mathcal{P}$ which, combined, it implies that it is invariant under time-reversal $\mathcal{T}$.

The same consideration applies in the case of a γ_5 mass term in which case the one-particle Dirac Hamiltonian now is

$$h = \begin{pmatrix} p & -im_5 \\ im_5 & -p \end{pmatrix}. \quad (153)$$

This Hamiltonian now anticommutes with the Pauli matrix σ_1 which also implies that the same charge conjugation symmetry C , $|E\rangle \leftrightarrow |-E\rangle$ is present in the spectrum of the case of a γ_5 mass. We can also repeat the argument on parity invariance $\mathcal{P}$, which is now multiplication by σ_1 . Thus the theory is invariant under time-reversal $\mathcal{T}$.

However, if the theory has both a Dirac mass m and a γ_5 mass m_5 , these symmetries are broken. Indeed, the one-particle Dirac Hamiltonian now is

$$h = \begin{pmatrix} p & m - im_5 \\ m + im_5 & -p \end{pmatrix} = p\sigma_3 + m\sigma_1 + m_5\sigma_2 \quad (154)$$

which no longer has a spectral symmetry. In this case $C\mathcal{P}$ is broken and, hence, so is $\mathcal{T}$ since $C\mathcal{P}\mathcal{T}$ remains unbroken (as it should).

In a lattice system, this is a symmetry transformation only if $\theta = \pi n/p_F$ is a lattice displacement, which restricts the allowed values of the chiral angle to be discrete. Although this is true, interactions play a significant role in the actual behavior. In fact, there are physical situations in which an effective continuous symmetry actually emerges in the infrared (long-distance) limit. This is what happens when the CDW is incommensurate and, as we will see in the next section, it slides under the action of an electric field.

In the case of a half-filled system (with only nearest-neighbor hopping matrix elements) the Fermi wave vectors are $\pm \pi/2$. In this case the allowed discrete chiral transformation has a chiral angle $\pi/2$ under which $\bar{\psi}\psi \mapsto -\bar{\psi}\psi$ (and similarly for $i\bar{\psi}\gamma_5\psi$) corresponding by a translation by one lattice spacing. The allowed four fermion operator is $(\bar{\psi}\psi)^2$. If the lattice fermions are spinless this operator reduces to

$$(\bar{\psi}\psi)^2 = -2j_R(x)j_L(x) + \lim_{\gamma \rightarrow x} \psi_R^\dagger(x)\psi_L^\dagger(x)\psi_L(\gamma)\psi_R(\gamma) + \text{h.c.} \quad (155)$$

where introduced the right and left moving (chiral) components of the current operator

$$j_R(x) = \frac{1}{2}(j_0(x) + j_1(x)) = \psi_R^\dagger(x)\psi_R(x), \quad j_L(x) = \frac{1}{2}(j_0(x) - j_1(x)) = \psi_L^\dagger(x)\psi_L(x) \quad (156)$$

The first term in Eq. (155) is known as the backscattering interaction and has scaling dimension 2. Hence, it is a marginal operator. The theory with only the first term is known in condensed matter physics as the Luttinger model and in High-Energy Physics as the (massless) Thirring model. The second operator in Eq. (155) formally violates momentum conservation as its total momentum is $4p_F = 2\pi$, which is a reciprocal lattice vector and, as such, it is equivalent to zero (mod 2π). Such an operator is not formally allowed in a (naive) continuum theory. This operator is due to a lattice Umklapp process and breaks the formal continuous chiral symmetry to a discrete $\mathbb{Z}_2$ subgroup. Although the naive scaling dimension of this operator is 2 (and hence it is formally marginal). If the fermions are spinless, the leading operator actually vanishes and the leading nonvanishing operator actually has dimension 4, which is irrelevant. However, as shown above, backscattering processes of the form $j_R(x) j_L(x)$ are part of this operator and are exactly marginal.

If the interaction is strong enough, the backscattering interaction can make the Umklapp operator relevant. When this happens, the fermionic system has a quantum phase transition to an insulating state with a period 2 (commensurate) CDW state. On the other hand, for spin 1/2 fermions, the operator $(\bar{\psi}\psi)^2$ is allowed and is marginally relevant. If the interactions are repulsive, the resulting state is an antiferromagnetic Néel state at quantum criticality, while for attractive interactions it is a period 2 CDW. This is what happens in the 1D Hubbard model (see, e.g., [Fradkin, 2013](#) for a detailed analysis).

There are two theories in relativistic systems, which are closely related to this problem. One is the Gross–Neveu model ([Gross and Neveu, 1974](#)) which is a theory of N species of massless Dirac spinors with Lagrangian density

$$\mathcal{L}_{\text{GN}} = \bar{\psi}_a i \partial \psi_a + g (\bar{\psi}_a \psi_a)^2 \quad (157)$$

with $a = 1, \dots, N$ (summation of repeated indices is implied). The spin-1/2 Hubbard model corresponds to the case $N = 2$. This Lagrangian is invariant only under the discrete chiral symmetry $\bar{\psi}_a \psi_a \mapsto -\bar{\psi}_a \psi_a$. This is a discrete, $\mathbb{Z}_2$, symmetry and as such it can be spontaneously broken in 1+1 dimensions. For $N \geq 2$, the resulting state has a (dynamically) broken $\mathbb{Z}_2$ chiral symmetry and that there is a chiral condensate $\langle \bar{\psi}_a \psi_a \rangle \neq 0$ corresponding to a period 2 CDW.

The other theory is known as the chiral Gross–Neveu model whose Lagrangian density is

$$\mathcal{L}_{\text{cGN}} = \bar{\psi}_a i \partial \psi_a + g \left((\bar{\psi}_a \psi_a)^2 - (\bar{\psi}_a \gamma_5 \psi_a)^2 \right) \quad (158)$$

which has the full continuous chiral symmetry. For $N = 1$, this theory is equivalent to the Luttinger model (and to the Gross–Neveu model if we ignore the Umklapp term). For $N \geq 2$ the chiral symmetry is formally broken. If this were true, this theory would violate the Mermin–Wagner theorem. However a detailed study (most easily done using bosonization methods) shows that instead of long-range order the correlator of both mass terms decay as a power law as a function of distance, consistent with the requirements by this theorem.

We close this section by noting that if the lattice model is not half filled but its density is either incommensurate or has a higher degree of commensurability, say p/q , the chiral symmetry is actually continuous (in the incommensurate case) or effectively continuous since the requisite Umklapp terms are strongly irrelevant. However, if the lattice model is not at half filling charge conjugation symmetry C is broken at the lattice scale (in the UV), where it is equivalent to particle–hole symmetry, but it is recovered in the low-energy, IR, regime (up to irrelevant operators). In this sense, both the continuous chiral symmetry and charge conjugation symmetry can be regarded as emergent IR symmetries

The chiral anomaly

In Section “Chiral symmetry and chiral symmetry breaking” we showed that the theory of massless Dirac fermions, in addition to a global $U(1)$ gauge symmetry, has a second conservation law which we called a global $U(1)$ chiral symmetry, shown in Eq. (131). This symmetry implies that there is a locally associated chiral current j_μ^5 given by

$$j_\mu^5(x) = \bar{\psi}(x) \gamma_\mu \gamma_5 \psi(x) \quad (159)$$

which also satisfies a continuity equation

$$\partial^\mu j_\mu^5 = 0 \quad (160)$$

and there is a globally conserved chiral charge Q^5

$$Q^5 = \int_{-\infty}^{\infty} dx j_0^5(x) = \int_{-\infty}^{\infty} dx (\psi_R^\dagger \psi_R - \psi_L^\dagger \psi_L). \quad (161)$$

It is easy to check that the Dirac current j_μ and the chiral current j_μ^5 are related by

$$j_\mu^5 = \epsilon_{\mu\nu} j^\nu \quad (162)$$

where $\epsilon_{\mu\nu}$ is the second rank Levi-Civita tensor.

The simultaneous conservation of both currents j_μ and j_μ^5 in the massless Dirac theory implies that the right and left moving densities j_R and j_L , defined in Eq. (156), should be separately conserved. In fact, if the Dirac theory has a mass term

$$\mathcal{L} = \bar{\psi} i \partial \psi - m \bar{\psi} \psi \quad (163)$$

it is straightforward to show that

$$\partial^\mu j_\mu^5 = 2mi \bar{\psi} \gamma^5 \psi \quad (164)$$

which means that in the massive theory, the axial current is not conserved. This is easy to understand since the mass term mixes the right and left moving components of the Dirac spinor and, hence, the right and left moving densities are not conserved.

What happens in the *massless* limit, $m \rightarrow 0$, is more subtle. This problem was investigated in the late 1960s in 3+1 dimensions by Adler (1969) and by Bell and Jackiw (1969), who were interested in the anomalous decay of a neutral pion into two photons, $\pi^0 \rightarrow 2\gamma$. This process appears at third order of perturbation theory and it involves the computation of a triangle diagram (a fermion loop). In 3+1 dimensions, this process has a UV divergence which needed to be regulated. These authors showed that it is not possible to find a regularization in which both the Dirac (gauge) current $j_\mu = \bar{\psi} \gamma_\mu \psi$ and the axial current $j_\mu^5 = \bar{\psi} \gamma_\mu \gamma^5 \psi$ are conserved. In other words, if gauge invariance is preserved then the axial current is not and has an *anomaly* and results in a nonconservation of the axial current, $\partial^\mu j_\mu^5 \neq 0$. On the other hand, at least in the case of the physical gauge-invariant regularization, the obtained expression for the anomaly in the axial current is *universal*, independent of the value of the UV regulator (the cutoff). Sometime later G. 't Hooft showed that in non-Abelian gauge theories instant processes also lead to anomalies and, furthermore, the result was also universal ('t Hooft, 1976a, b). Since the result is universal and, hence, independent of the UV scale, this led to the concept of anomaly matching conditions.

We will examine this problem in 1+1 dimensions (although it plays a key role in the theory of topological insulators in three space dimensions, Qi et al., 2008). As we noted above, the lattice model is gauge-invariant and has only one conserved current. The conserved axial current appeared only in the low-energy regime in which the lattice model is described by a theory of massless Dirac fermions. To understand this problem, we will consider the theory of fermions in 1+1 dimensions coupled to a $U(1)$ gauge field. In the presence of a background (i.e., not quantized) electromagnetic field in the $A_0 = 0$ gauge, the free fermion Hamiltonian of Eq. (116) becomes

$$H[A] = -t \sum_{n=1}^L c^\dagger(n) e^{ieA(n,t)/\hbar} c(n) + \text{h.c.} \quad (165)$$

An uniform and constant electric field is E , which is represented by a vector potential $A = -cEt$ (with c being the speed of light). The net effect of this gauge field is to shift of the momentum of the fermion quasiparticles $p \rightarrow p + ecEt/\hbar$ or, what is the same, to displace the fermion dispersion relation in momentum by the $ecEt/\hbar$. This means that the Fermi points are also shifted by that amount, $p_F \rightarrow p_F + ecEt/\hbar$ and $-p_F \rightarrow -p_F + ecEt/\hbar$. This means that the single particle states between p_F and $p_F + ecEt/\hbar$ that were empty for $E = 0$ are now occupied and the states between $-p_F$ and $-p_F + ecEt/\hbar$ that were occupied for $E = 0$ are now empty. This means that number of right-moving fermions is increasing at a rate of $ecE/\hbar$ and that the number of left-moving fermions decreases at the same rate. This results in a net current. Throughout this process the total number of fermions is not changed, gauge invariance is satisfied, but the number of right and left moving fermions is not separately concerned. Notice that this is an effect that involved the entire Fermi sea but the net effect is at low energies.

Let us see now how this plays out in the effective Dirac theory. The massless Dirac Lagrangian density in the background of an unquantized electromagnetic field A_μ is

$$\mathcal{L} = \bar{\psi} (i\partial - e\mathbf{A}) \psi. \quad (166)$$

Since there is no mass term, the Dirac equation still decouples into two equations, for the right and left moving components of the Dirac spinor. In the $A_0 = 0$, gauge they are

$$i\partial_0 \psi_R = (-i\partial_1 - A^1) \psi_R, \quad i\partial_0 \psi_L = (i\partial_1 - A^1) \psi_L. \quad (167)$$

In the temporal gauge, $A_0 = 0$, a uniform electric field $E = \partial_0 A^1$, and A^1 increases linearly with time. As A^1 increases, the Fermi momentum p_F (which is equal to the Fermi energy E_F) also increases at the rate eE . The density of states of a system of length L is $L/(2\pi)$. So, the rate of change of the number of right-moving fermions is

$$\frac{dN_R}{dx_0} = \frac{e}{2\pi} E \quad (168)$$

where we defined $N_R = \int_0^L dx j_R$ and similarly for N_L . If the UV regulator of the theory is compatible with gauge invariance, then the total fermion number must be conserved and the total vacuum charge must remain equal to zero,

$$Q = \int_0^L dx j_0(x) = N_R + N_L = 0. \quad (169)$$

Thus, if N_R increases, then N_L must decrease by the same amount. Or, equivalently, the electric field E creates an equal number of particles N_R and of antiparticles $\bar{N}_L = -N_L$.

On the other hand, the chiral charge $Q^5 = N_R - N_L$ must increase at the rate

$$\frac{dQ^5}{dx_0} = \frac{dN_R}{dx_0} + \frac{dN_L}{dx_0} = \frac{e}{\pi} E. \quad (170)$$

Again, the details of the UV regularization do not matter, only that it is gauge-invariant. We can also interpret Eq. (170) as the rate of particle–antiparticle pair creation by an electric field.

In a relativistic notation, these results are expressed as

$$\partial^\mu j_\mu^5 = \frac{e}{2\pi} \epsilon_{\mu\nu} F^{\mu\nu}. \quad (171)$$

Hence, the formally conserved current j_μ^5 has an anomaly and is not conserved due to quantum effects. Since it is not conserved, we cannot gauge the chiral symmetry. In the next section, we will see that the anomaly is closely related with bosonization.

Bosonization, anomalies, and duality

We will reexamine the problem at hand from the point of view of the fermionic currents of the Dirac theory j_μ as operators. Since the currents obey the continuity equation, $\partial_\mu j^\mu = 0$ one expects that this would imply that it may be possible to write them as a curl of a scalar field, that is, $j_\mu(x) = \epsilon_{\mu\nu} \partial^\nu \phi(x)$ where $\phi(x)$ should be a scalar field. Since this should be an operator identity, we will need to understand how the currents act on the physical Hilbert space.

The Fermi-Bose mapping in 1D systems is closely related to the chiral anomaly we just discussed. Bosonization of a system of 1+1 dimensional massless Dirac fermions is a set of operator identities understood as matrix elements of the observables in the physical Hilbert space. These identities were first derived by [Mattis and Lieb \(1965\)](#), based on earlier work by [Schwinger \(1959\)](#). These identities were rediscovered (and their scope greatly expanded) by [Luther and Emery \(1974\)](#), by [Coleman \(1975\)](#), by [Mandelstam \(1975\)](#), and by [Witten \(1978\)](#). A non-Abelian version of bosonization was subsequently derived by [Witten \(1984\)](#).

The physical Hilbert space is defined as follows: Let $|\text{FS}\rangle \equiv |0\rangle$ denote the *filled Fermi sea*. In what follows we will assume that the physical system is macroscopically large and that local operators create the physical states by acting *finitely* on the filled Fermi sea. Physical observables, such as the right and left moving densities $j_R(x)$ and $j_L(x)$, need to be *normal-ordered* with respect to the physical vacuum state, the filled Fermi (Dirac) sea $|0\rangle$. The normal ordered densities are $j_R(x) : \equiv j_R(x) - \langle 0 | j_R(x) | 0 \rangle$ and $j_L(x) : \equiv j_L(x) - \langle 0 | j_L(x) | 0 \rangle$. Since the densities are products of fermion operators, they need to be defined as a limit in which the operators are separated by a short distance η . Crucial to this construction is that the computation of the expectation values be regularized in such a way that the charge (gauge) current $j_\mu(x)$ is locally conserved and satisfies the continuity equation $\partial_\mu j^\mu = 0$ as an operator identity. In what follows, all expectation values will refer to the filled Fermi sea state $|0\rangle$.

The propagators of the right and left moving Fermi fields are given by

$$\langle \psi_R^\dagger(x_0, x_1) \psi_R(0, 0) \rangle = \frac{-i}{2\pi(x_0 - x_1 + i\epsilon)}, \quad \langle \psi_L^\dagger(x_0, x_1) \psi_L(0, 0) \rangle = \frac{i}{2\pi(x_0 + x_1 + i\epsilon)} \quad (172)$$

The expectation values of the currents at a space location x_1 are

$$\langle j_R(x_1) \rangle = \lim_{\eta \rightarrow 0} \langle \psi_R^\dagger(x_1 + \eta) \psi_R(x_1 - \eta) \rangle = \frac{i}{4\pi\eta}, \quad \langle j_L(x_1) \rangle = \lim_{\eta \rightarrow 0} \langle \psi_L^\dagger(x_1 + \eta) \psi_L(x_1 - \eta) \rangle = \frac{-i}{4\pi\eta} \quad (173)$$

which are divergent at short distances. It follows that the normal-ordered right and left moving current densities satisfy the equal-time commutation relations

$$[j_R(x_1), j_R(x'_1)] = -\frac{i}{2\pi} \partial_1 \delta(x_1 - x'_1), \quad [j_L(x_1), j_L(x'_1)] = +\frac{i}{2\pi} \partial_1 \delta(x_1 - x'_1) \quad (174)$$

These identities imply that the normal-ordered space-time components of the current $j_\mu = (j_0, j_1)$ satisfy the equal-time commutation relations

$$[j_0(x_1), j_1(x'_1)] = -\frac{i}{\pi} \partial_1 \delta(x_1 - x'_1), \quad [j_0(x_1), j_0(x'_1)] = [j_1(x_1), j_1(x'_1)] = 0 \quad (175)$$

The nonvanishing right-hand sides of these commutators are known as Schwinger terms. These identities define the $U(1)$ (Kac-Moody) current algebra.

We should note that in a theory of *nonrelativistic* Fermi fields $\psi(\mathbf{x}, t)$ in all dimensions, the charge density $\rho(\mathbf{x})$ and the current operators $\mathbf{j}(\mathbf{x}) = \frac{1}{2i} (\psi^\dagger(\mathbf{x}) \nabla \psi(\mathbf{x}) - \nabla \psi^\dagger(\mathbf{x}) \psi(\mathbf{x}))$ satisfy a similar expression (also at equal times)

$$[\rho(\mathbf{x}), j_k(\mathbf{x}')] = -i \frac{e^2}{mc^2} \partial_k (\delta(\mathbf{x} - \mathbf{x}') \rho(\mathbf{x})), \quad [\rho(\mathbf{x}), \rho(\mathbf{x}')] = 0, \quad [j_k(\mathbf{x}), j_l(\mathbf{x}')] = 0 \quad (176)$$

In one dimension, and in the regime in which the fermions have a macroscopic density so that $\rho(\mathbf{x}) \simeq \langle \rho(\mathbf{x}) \rangle$, after a multiplicative rescaling of the operators, the nonrelativistic identities of Eq. (176) are equivalent to the $U(1)$ current algebra of Eq. (175).

The $U(1)$ current algebra of Eq. (175) is reminiscent of the equal-time canonical commutation relations of a scalar field. Indeed, if $\phi(x)$ is a scalar field and $\Pi(x) = \partial_0 \phi(x)$ is its canonically conjugate momentum, then they obey the equal-time canonical commutation relations

$$[\phi(x_1), \Pi(x'_1)] = i\delta(x_1 - x'_1). \quad (177)$$

We can then identify the charge density j_0 and the current density j_1 with the scalar field operators

$$j_0(x) = \frac{1}{\sqrt{\pi}} \partial_1 \phi(x), \quad j_1(x) = -\frac{1}{\sqrt{\pi}} \Pi(x) = -\frac{1}{\sqrt{\pi}} \partial_0 \phi(x) \quad (178)$$

which obey the $U(1)$ current algebra of Eq. (175) as a consequence of the canonical commutation relations, Eq. (177). Furthermore, we can rewrite Eq. (177) in the Lorentz covariant form

$$j_\mu(x) = \frac{1}{\sqrt{\pi}} \epsilon_{\mu\nu} \partial^\nu \phi(x) \quad (179)$$

which is clearly consistent with the local conservation of the current j_μ

$$\partial_\mu j^\mu(x) = 0. \quad (180)$$

Let us examine now the question of the conservation of the chiral current j_μ^5 . In Eq. (162), we showed that the gauge current and the chiral current are related by $j_\mu^5 = \epsilon_{\mu\nu} j^\nu$. Therefore the divergence of the chiral current is

$$\partial^\mu j_\mu^5 = \epsilon_{\mu\nu} \partial^\mu j^\nu = \frac{1}{\sqrt{\pi}} \epsilon_{\mu\nu} \epsilon^{\nu\lambda} \partial^\mu \partial_\lambda \phi = -\frac{1}{\sqrt{\pi}} \partial^2 \phi \quad (181)$$

where we used the identification of the gauge current in terms of the scalar field ϕ , Eq. (179). Therefore we conclude that

$$\partial^\mu j_\mu^5 = 0 \Leftrightarrow \partial^2 \phi = 0. \quad (182)$$

This equation states that the chiral current as an operator identity is conserved if and only if the field ϕ is a free massless scalar field, whose Lagrangian density is

$$\mathcal{L}_B = \frac{1}{2} (\partial_\mu \phi)^2. \quad (183)$$

In Eq. (166), we considered the free massless Dirac Lagrangian coupled to a background (not quantized) gauge field A_μ through the usual minimal coupling which here is $\mathcal{L}_{\text{int}} = -e j_\mu A^\mu$. using the bosonization identity for the gauge current, Eq. (179) we see that the Lagrangian density of the bosonized theory now becomes

$$\begin{aligned} \mathcal{L}_B[A] &= \frac{1}{2} (\partial_\mu \phi)^2 - \frac{e}{\sqrt{\pi}} \epsilon_{\mu\nu} \partial^\nu \phi(x) A^\mu(x) \\ &\equiv \frac{1}{2} (\partial_\mu \phi)^2 + J(x) \phi(x) \end{aligned} \quad (184)$$

where the source $J(x)$ is

$$J(x) = \frac{e}{\sqrt{\pi}} \epsilon_{\mu\nu} \partial^\nu A^\mu(x) = \frac{e}{\sqrt{4\pi}} F^*(x) \quad (185)$$

where $F^*(x) = \epsilon_{\mu\nu} F^{\mu\nu}(x)$ is the (Hodge) dual of the field strength $F_{\mu\nu}$. Hence, F^* is (essentially) the source for the scalar field $\phi(x)$. This implies that the equation of motion of the scalar field must be

$$-\partial^2 \phi(x) = J(x) = \frac{e}{\sqrt{\pi}} \epsilon_{\mu\nu} \partial^\nu A^\mu. \quad (186)$$

Retracing our steps, we find that the chiral current j_μ^5 obeys

$$\partial^\mu j_\mu^5 = -\frac{1}{\sqrt{\pi}} \partial^2 \phi = \frac{e}{2\pi} \epsilon_{\mu\nu} F^{\mu\nu} \quad (187)$$

which reproduces the chiral anomaly given in Eq. (170).

These results suggest that the theory of a free massless Dirac spinor must be equivalent to the theory of the free massless scalar field. This statement is known as bosonization. However for this identification to be correct, there must be an identification of the Hilbert spaces and of all the operators of each theory. We will not do this detailed analysis here but will highlight the most significant statements.

Let us begin with the fermion number of the Dirac theory. Consider a system of fermions of total length L . Using the bosonization identity of Eq. (179), we find that the fermion number $N_F \equiv Q$ is given by

$$N_F = \int_0^L dx_1 j_0(x_0, x_1) = \frac{1}{\sqrt{\pi}} \int_0^L dx_1 \partial_1 \phi(x_0, x_1) = \frac{1}{\sqrt{\pi}} (\phi(x_0, L) - \phi(x_0, 0)). \quad (188)$$

Thus, the vacuum sector of the Dirac theory, with $N_F = 0$, corresponds to the theory of the scalar field with periodic boundary conditions, $\phi(x_1 = 0) = \phi(x_1 = L)$. Furthermore, since the fermion number is quantized, $N_F \in \mathbb{Z}$, changing the fermion number is the same as twisting the boundary conditions of the scalar so that

$$\phi(x_1 + L) = \phi(x_1) + \sqrt{\pi} N_F. \quad (189)$$

In String Theory (Polchinski, 1998) the scalar field is interpreted as the coordinate of a string. Compactifying the space where the string lives to be a circle of radius R means that the string coordinate is defined modulo $2\pi R n$, where n is an integer. We see that the condition imposed by Eq. (189) is equivalent to say that the scalar field is *compactified* and that the compactification radius is $R = 1/\sqrt{4\pi}$. This identification also imposes the restriction that the allowed operators of the scalar field must obey the identification

$$\phi(x) \sim \phi(x) + 2\pi R n \quad (190)$$

as an equivalency condition.

The simplest bosonic operators that obey the compactification condition are the vertex operators $V_\alpha(x)$,

$$V_\alpha(x) = \exp(i\alpha\phi(x)). \quad (191)$$

The compactification condition then requires that the allowed vertex operators should have $\alpha = n/R = \sqrt{4\pi} n$, where n is an integer. Since the propagator of the scalar field in 1+1-dimensional (Euclidean) spacetime is

$$G(x - x') = -\frac{1}{2\pi} \ln\left(\frac{|x - x'|}{a}\right) \quad (192)$$

where a is a short-distance cutoff, we find that the scaling dimension of the vertex operator is $\Delta_\alpha = \alpha^2/(4\pi) = n^2$. We will see shortly that the vertex operator with $\alpha = \sqrt{4\pi}$ is essentially the Dirac mass operator (which has scaling dimension 1).

The free massless scalar field can be decomposed into right and left moving components, ϕ_R and ϕ_L respectively,

$$\phi = \phi_R + \phi_L, \quad \vartheta = -\phi_R + \phi_L \quad (193)$$

where

$$\vartheta(x_0, x_1) = \int_{-\infty}^{x_1} dx'_1 \Pi(x_0, x'_1) \quad (194)$$

is the Cauchy–Riemann dual of the field $\phi(x)$ since they satisfy the Cauchy–Riemann equation

$$\partial_\mu \phi = \epsilon_{\mu\nu} \partial^\nu \vartheta. \quad (195)$$

The right and left moving components of the Dirac spinor are found to have the bosonized expression (Mandelstam, 1975)

$$\psi_R(x) = \frac{1}{\sqrt{2\pi a}} : \exp(i\sqrt{4\pi}\phi_R(x)) : , \quad \psi_L(x) = \frac{1}{\sqrt{2\pi a}} : \exp(-i\sqrt{4\pi}\phi_L(x)) : \quad (196)$$

It is easy to check that the propagators of these operators agree with the expressions given in Eq. (172), and that they have scaling dimension 1/2 and spin 1/2.

How does a chiral transformation act on the scalar field? A chiral transformation by an angle θ , c.f. Eq. (132), acts on the right and moving fermions as $\psi'_R = \exp(i\theta)\psi_R$ and $\psi'_L = \exp(-i\theta)\psi_L$. From Eq. (196), we see that the right and left moving components of the scalar field transform as $\phi'_R = \phi_R + \theta/\sqrt{4\pi}$ and $\phi'_L = \phi_L + \theta/\sqrt{4\pi}$. This means that a chiral transformation by an angle θ of the Dirac fermion is equivalent to a translation (a shift) of the scalar field $\phi' = \phi + 2\theta/\sqrt{4\pi}$.

We can use the operator product expansion discussed in Section “The operator product expansion” to show that the fermion mass terms $\bar{\psi}\psi$ and $i\bar{\psi}\gamma^5\psi$ are given by the following identifications

$$\bar{\psi}\psi = \frac{1}{2\pi a} : \cos(\sqrt{4\pi}\phi) : , \quad i\bar{\psi}\gamma^5\psi = : \sin(\sqrt{4\pi}\phi) : . \quad (197)$$

These operators have scaling dimension 1 and transform properly under chiral transformations. These identifications imply that a theory of free *massive* Dirac fermions

$$\mathcal{L}_D = \bar{\psi} i \not{\partial} \psi - m \bar{\psi} \psi \quad (198)$$

is equivalent to the sine-Gordon field theory (Coleman, 1975) whose Lagrangian is

$$\mathcal{L}_{SG} = \frac{1}{2} (\partial_\mu \phi)^2 - g : \cos(\sqrt{4\pi}\phi) : \quad (199)$$

where $g = m/(2\pi a)$.

Given the central role played by the current algebra identities of Eq. (175), one may wonder if a similar approach might apply in higher dimensions. Schwinger terms in current algebra play an important role in relativistic field theories. However in higher dimensions, their structure is more complex and does not lead to identities of the type we have discussed. The reason at the root of this problem is largely kinematical. The Bose (scalar) field ϕ is qualitatively a bound state, a collective mode in the language of condensed matter physics. In 1+1 dimensions, this collective mode exhausts the spectrum at low energies due to the strong kinematical restriction on one spatial dimension.

The equivalency between the theory of free massive Dirac fermions and the sine-Gordon theory is an example of the power of bosonization. On the Dirac side, mapping the theory is free and its spectrum is well understood. But on the sine-Gordon side, the theory is nonlinear. In fact in the sine-Gordon theory, the fermions are essentially solitons, domain walls of the scalar field. For these and many other reasons that we do not have space here bosonization plays a huge role in understanding the nonperturbative behavior of systems both in condensed matter physics and in Quantum Field Theory in 1+1 dimensions. We will see in Section “Bosonization of the Dirac theory in 2+1 dimensions” that to an extent some of these ideas can and have been extended to relativistic systems and classical statistical mechanical systems in 2+1 dimensions.

Fractional charge

Solitons in one dimensions

We begin by returning to the equivalency between the theory of free massive Dirac fermions and sine-Gordon theory, in 1+1 dimensions. In Eq. (188), we showed that the boundary conditions of the compactified scalar field $\phi(x)$ are determined by the fermion number N_F of the dual Dirac theory, and that the vacuum sector of the Dirac theory maps onto the sine-Gordon theory with periodic boundary conditions. We will now examine the sector with one fermion, $N_F = 1$. This sector of the Dirac theory maps onto the sine-Gordon theory with *twisted* boundary conditions,

$$\phi(L) - \phi(0) = \sqrt{\pi}. \quad (200)$$

The Hamiltonian of the sine-Gordon theory is

$$H_{\text{SG}} = \int_{-\infty}^{\infty} dx \left[\frac{1}{2} \Pi^2(x) + \frac{1}{2} (\partial_x \phi(x))^2 + g \cos(\sqrt{4\pi} \phi(x)) \right] \quad (201)$$

In the sector with periodic boundary conditions, the classical ground states are static and uniform configurations that minimize the potential energy. Since the potential energy is a periodic functional of $\phi(x)$, the classical minima are at $\phi_n(x) = (n + 1/2)\sqrt{\pi}$, where n is an arbitrary integer. The classical energy of these ground states is extensive and is given by $E_{\text{gnd}} = -gL$ where L is the linear size of the system.

The classical ground state in the twisted sector is a *domain wall* (or *soliton*) that interpolates between the static and uniform ground states $\phi(x) = \pm\sqrt{\pi}/2$. The classical ground state in this sector is the static solution of the Euler-Lagrange equation

$$\frac{d^2 \phi}{dx^2} = -2g\sqrt{\pi} \sin(2\sqrt{\pi} \phi(x)) \quad (202)$$

such that asymptotically satisfies $\lim_{x \rightarrow \pm\infty} \phi = \pm\sqrt{\pi}/2$. The solution is the classical soliton configuration

$$\phi(x) = \frac{\sqrt{\pi}}{2} \tan^{-1}(\exp(2\sqrt{\pi}g(x - x_0))) - \frac{\sqrt{\pi}}{2} \quad (203)$$

The soliton solution represents a *domain wall* between two symmetry-related classical ground states with $\phi = \pm\sqrt{\pi}/2$.

The energy of the soliton (measured from the energy of the ground state in the trivial sector) is finite and is given by

$$E_{\text{soliton}} = 4\sqrt{\frac{g}{\pi}} \quad (204)$$

where x_0 is a zero mode of the soliton solution and represents its coordinate. By coupling the bosonized theory to a weak electromagnetic field A_μ as given in Eq. (184), it is easy to check that it has electric charge $-e$ and, in this sense represents the electron. Then the identities of Eq. (196) can be used that as a quantum state it is indeed a fermion.

Polyacetylene

In Section “Bosonization, anomalies, and duality,” we saw that solitons of a scalar field can be regarded as being equivalent to electrons, fermions with charge $-e$. We will now see that in a theory of fermions coupled to a domain wall of a scalar field, the soliton carries fractional charge. This problem has been extensively studied in one-dimensional conductors such as polyacetylene, in

particular by the work of Su et al. (1979) and by Jackiw and Schrieffer (1981). In quantum field theory, this problem was first discussed by Jackiw and Rebbi (1976) and by Goldstone and Wilczek (1981).

In Section “Dirac fermions in one space dimensions,” we showed that the physics of lattice fermions in one dimension at low energies is well described by a theory of massless Dirac fermions. In a one-dimensional conductor, such as polyacetylene, the fermions couple to the lattice vibrations (phonons). Su, Schrieffer, and Heeger (SSH) (Su et al., 1979) proposed a simple model in which the electrons couple to the lattice vibrations through a modulation of the hopping amplitude between two consecutive sites n and $n + 1$, instead of being a constant t , becomes $t_{n,n+1} = t - g(u_{n+1} - u_n)$, where u_n is the displacement of the ion (a CH group in polyacetylene) at site n from its classical equilibrium position and g is the electron–phonon coupling constant. In polyacetylene, the number of electrons (which are spin-1/2 fermions) is equal to the number of sites of the lattice and the electronic band is half-filled. At half filling, this simple band structure is invariant under a particle–hole transformation. If the coupling to the lattice vibrations is included, this symmetry remains respected provided the displacements change sign $u_n \rightarrow -u_n$ for all lattice sites. In polyacetylene, the lattice dimerizes (a process known as a Peierls distortion) and the discrete translation symmetry by one lattice spacing is spontaneously broken: the system becomes a period 2 CDW on the bonds of the lattice. The broken symmetry state is still invariant under a particle–hole transformation.

The effective field theory of this system is a theory of two Dirac spinors $\psi_{\alpha,\sigma}(x)$, where $\alpha = 1, 2$ denotes right and left-moving fermions, and $\sigma = \uparrow, \downarrow$ are the two spin polarizations. The Lagrangian density of this system is

$$\mathcal{L} = \bar{\psi}_\sigma i \partial_t \psi_\sigma - g \phi(x) \bar{\psi}_\sigma(x) \psi_\sigma(x) - \frac{1}{2} \phi(x)^2. \quad (205)$$

The real scalar field $\phi(x)$ represents the distortion field of the polyacetylene chain. Here we will assume that the chains have spontaneously distorted and we will regard the scalar field as static and classical. This is a good approximation since the masses of the CH complexes are much bigger than the electron mass. This continuum model is due to Takayama et al. (1980) and further developed by Campbell and Bishop (1981, 1982). Many of the results found in this (adiabatic) approximation remain qualitatively correct upon taking into account the quantum dynamics of the chain, even in the limit in which the ions are treated as being “light” (provided the spin of the fermions is taken into account) (Hirsch and Fradkin, 1982; Fradkin and Hirsch, 1983).

In the field theory, the discrete symmetry of displacements by one lattice spacing becomes the $\mathbb{Z}_2$ symmetry $\phi \rightarrow -\phi$. This is a symmetry of the electron–phonon system once combined with the discrete chiral transformation $\psi \rightarrow \gamma_5 \psi$ under which $\bar{\psi} \rightarrow -\bar{\psi}$. The ground state is twofold degenerate $\pm \phi_0$ with

$$\phi_0 = \frac{2\Lambda v_F}{g} \exp\left(-\frac{\pi v_F}{g^2}\right) \quad (206)$$

and the Dirac fermion (the electron) has an exponentially small mass, $m = g\phi_0$.

Fractionally charged solitons

Jackiw and Rebbi showed that the 1+1-dimensional classical ϕ^4 theory has the following soliton solution that interpolates between the two classically ordered states at $\pm \phi_0$ (Jackiw and Rebbi, 1976)

$$\phi(x) = \phi_0 \tanh\left(\frac{x - x_0}{\xi}\right) \quad (207)$$

where ξ is the correlation length of ϕ^4 theory, and x_0 is the (arbitrary) location of the soliton. They further showed that, when coupled to a theory of massless relativistic fermions through a Yukawa coupling, as in Eq. (205), this soliton carries fractional charge. The argument goes as follows. The one-particle Dirac Hamiltonian for a Dirac fermion with a position-dependent mass $m(x)$ is

$$H = -i\sigma_1 \partial_x + m(x)\sigma_3 = \begin{pmatrix} m(x) & -i\partial_x \\ -i\partial_x & -m(x) \end{pmatrix} \quad (208)$$

where $m(x) = g\phi(x)$, with $\phi(x)$ being the soliton solution of Eq. (207). This Hamiltonian is Hermitian and real. Furthermore, this Hamiltonian anticommutes with the Pauli matrix σ_2 . This implies that for every positive-energy state $|E\rangle$ with energy $+E$, there is a negative-energy eigenstate with energy $-E$ given by $\sigma_2|E\rangle$. Hence, the spectrum is particle–hole symmetric (or, what is the same, charge-conjugation invariant). In addition, and consistent with charge-conjugation symmetry, the Hamiltonian of Eq. (208) has a state with $E = 0$, a zero mode, with a normalizable spinor wave function

$$\psi_0(x) = \frac{1}{\sqrt{2}} \begin{pmatrix} -i \\ 1 \end{pmatrix} \exp\left(-\text{sgn}(m) \int_0^x dx' m(x')\right) \quad (209)$$

which exists for an arbitrary function $m(x)$, which changes sign once at some location (which we took to be $x_0 = 0$). Jackiw and Rebbi further showed that the soliton (antisoliton) carries fractional charge

$$Q = \mp \frac{e}{2}. \quad (210)$$

This result follows from the spectral asymmetry identity of the density of states $\rho_s(E)$ in the presence of the soliton

$$Q = -\frac{e}{2} \int_0^\infty (\rho_s(E) - \rho_s(-E)) = -\frac{e}{2} \eta \quad (211)$$

where η is the spectral asymmetry of the Dirac operator in the soliton background, and it is known as the APS η -invariant of [Atiyah et al. \(1975\)](#). Given the one-to-one correspondence that exists between positive and negative energy states in the spectrum, the spectral asymmetry follows from the condition that the zero mode be half-filled, which is required by normal ordering or, what is the same, by charge neutrality. Another way to understand this result is that adding (or removing) a fermion of charge $-e$ results in the creation of a soliton–antisoliton pair, with each topological excitation carrying half of the charge of the electron. In other words, in the dimerized phase, the electron is fractionalized. In this analysis, we ignored the spin of the electron. If we take it into account the spin degree of freedom, the soliton is instead a boson with charge $\mp e$.

There is an alternative, complementary, way to think about the charge of the soliton. [Goldstone and Wilczek \(1981\)](#) considered a theory in which the (massless) Dirac fermion is coupled to two real scalar fields, φ_1 and φ_2 , with Lagrangian

$$\mathcal{L} = \bar{\psi} i \partial \psi - g \varphi_1 \bar{\psi} \psi - i g \varphi_2 \bar{\psi} \gamma_5 \psi \equiv \bar{\psi} i \partial \psi - g |\varphi| \bar{\psi} \exp(i\theta \gamma_5) \psi \quad (212)$$

where $|\varphi|^2 = \varphi_1^2 + \varphi_2^2$ and $\theta = \tan^{-1}(\varphi_2/\varphi_1)$. They considered a soliton in which $g\varphi_1 = m$ is the constant (in space) Dirac mass and φ_2 winds slowly between two values $\pm \varphi_0$ for $x \rightarrow \pm\infty$. In this theory, the one-particle Dirac Hamiltonian is

$$H = -i\sigma_1 \partial_x + g\varphi_1 \sigma_3 + g\varphi_2 \sigma_2 \quad (213)$$

which is Hermitian and complex and, hence, it violates CP invariance.

A perturbative calculation of the induced (gauge-invariant) current j_μ , which is given by the triangle diagram of a fermion loop with two gauge field insertions and a coupling of the scalar fields, yields the result (with $a = 1, 2$)

$$\langle j_\mu(x) \rangle = \frac{1}{2\pi} \epsilon_{\mu\nu} \epsilon_{ab} \frac{\varphi_a \partial^\nu \varphi_b}{|\varphi|^2} = \frac{1}{2\pi} \epsilon_{\mu\nu} \partial^\nu \theta \quad (214)$$

which is locally conserved. Notice, however, that the induced axial current j_μ^5 is not conserved, $\partial^\mu \langle j_\mu^5 \rangle = -\frac{1}{2\pi} \partial^2 \theta \neq 0$ and, hence, this current is anomalous. We can now compute the total charge accumulated as the soliton is created adiabatically to be given by the Goldstone–Wilczek formula

$$Q = -e \frac{\Delta\theta}{2\pi} \quad (215)$$

where $\Delta\theta = \theta(+\infty) - \theta(-\infty)$. Since $\lim_{x \rightarrow \pm\infty} \varphi_2(x) = \pm\varphi_0$, we obtain the result

$$Q = -\frac{e}{\pi} \tan^{-1} \left(\frac{g\varphi_0}{m} \right). \quad (216)$$

In the limit $m = g\varphi \rightarrow 0$, where CP (or T) invariance is recovered, we get

$$\lim_{m \rightarrow 0} Q = -\frac{e}{2} \quad (217)$$

which is the Jackiw–Rebbi result for the fractional charge of a soliton of Eq. (210).

The results for the fractional charge of the soliton can also be derived using the bosonization identities of Section “Bosonization, anomalies, and duality.” Indeed, the bosonized expression for the Lagrangian of Eq. (212) is

$$\mathcal{L} = \frac{1}{2} (\partial_\mu \phi)^2 - \frac{g|\varphi|}{2\pi a} \cos(\sqrt{4\pi} \phi - \theta). \quad (218)$$

Deep in the phase in which the Bose field ϕ is massive, the nonlinear term in Eq. (218) locks this field to the chiral angle θ , that is,

$$\phi = \frac{1}{\sqrt{4\pi}} \theta. \quad (219)$$

However, the bosonization identities also tell us that the gauge current j_μ is given by the curl of the scalar field ϕ . Therefore, in this state the current j_μ is

$$j_\mu = \frac{1}{\sqrt{\pi}} \epsilon_{\mu\nu} \partial^\nu \phi = \frac{1}{2\pi} \epsilon_{\mu\nu} \partial^\nu \theta \quad (220)$$

which is the same as the Goldstone–Wilczek result of Eq. (214). That these two seemingly different approaches yield the same result is not accidental as they both follow from the axial anomaly.

Fractional statistics

A fundamental axiom of Quantum Mechanics is that identical particles are indistinguishable (Dirac, 1930; Landau and Lifshitz, 1957). In nonrelativistic Quantum Mechanics, this leads to the requirement that the quantum states of a system of identical particles must be eigenstates of the pairwise particle exchange operator. Since two exchanges are equivalent to the identity operation, this implies that the states must be even or odd under pairwise exchanges. This result, in turn, implies that particles can be classified as being either bosons (whose states are invariant under pairwise exchanges) or fermions (whose states change sign under pairwise particle exchanges). A consequence is that bosons obey the Bose-Einstein (and can condense into a single particle state) whereas fermions obey the Fermi–Dirac distribution and must obey the Pauli exclusion principle. It is an implicit assumption of this line of reasoning that all relevant states of a system of identical particles can be efficiently represented by a (suitably symmetrized or antisymmetrized) product state.

This classification is present at an even deeper level in (relativistic) Quantum Field Theory where locality, unitarity, and Lorentz invariance require that the fields be classified as representations of the Lorentz group and obey the Spin-Statistics Theorem (Weinberg, 2005). The Spin-Statistics Theorem is actually an *axiom* of local relativistic Quantum Field theory that requires that fields that transform with an integer spin representation of the Poincaré group (i.e., scalars, gauge fields, gravitational fields) must be bosons while fields that transform with a half-integer spin representation (i.e., Dirac spinors) must be fermions. This spin-statistics connection is intrinsic to the construction of String Theory Polchinski (1998).

Given these considerations, there was a general consensus that fermions and bosons were the only possible types of statistics. Nevertheless several exceptions to this rule were known to exist. One is the construction of the magnetic monopole in 3+1 dimensional gauge theory by Tai-Tsun Wu and Chen-Ning Yang who showed that a scalar coupled to a Dirac magnetic monopole behaves as a Dirac spinor (Wu and Yang, 1976). This was an early example of statistical transmutation by coupling a matter field to a nontrivial configuration of a gauge field. As we will note below, the construction of anyons (particles with fractional statistics) in 2+1 dimensions has a close parentage to the Wu-Yang example. Examples of statistical transmutation were known to exist in 1+1 dimensional theories where a system of hard-core bosons was shown to be equivalent to a theory of free fermions using the Jordan–Wigner transformation (Lieb et al., 1961), which represents a fermion as a composite operator of a hard-core boson and an operator that creates a kink (or soliton). This construction also underlies the fermion-boson mapping in 1+1 dimensional field theories (Mattis and Lieb, 1965; Luther and Emery, 1974; Coleman, 1975; Mandelstam, 1975) that we discussed in Section “Bosonization, anomalies, and duality.” Finally, in the late 1970s, it was found that 1+1 dimensional $\mathbb{Z}_N$ spin systems harbor operators known as parafermions, which obey the same algebra shortly afterwards found to be obeyed by anyons in 2+1 dimensions (Fradkin and Kadanoff, 1980).

Basics of fractional statistics

Jon Magne Leinaas and Jan Myrheim wrote an insightful paper in 1977 in which they examined the structure of the configuration space of the histories of a system of N identical particles (Leinaas and Myrheim, 1977). Using the Feynman path-integral approach, they showed that if the worldlines of the identical particles are not allowed to cross, then the configuration space is topologically nontrivial. Through a detailed analysis they showed that the three and higher dimensions under a pairwise particle exchange the states must be either even or odd and hence the particles are either bosons or fermions. Leinaas and Myrheim also showed that in one and two space dimensions, the wave functions can change by a *phase*, nowadays known as the statistical angle. In retrospect this result could have been anticipated (but was not) in an earlier paper by Laidlaw and DeWitt (1971), who did a similar analysis of the configuration space of identical particles in the Feynman path integral.

Frank Wilczek generalized the Aharonov–Bohm effect (Aharonov and Bohm, 1959) to describe the quantum mechanics of composite objects made of electric charge and magnetic flux in two space dimensions (Wilczek, 1982a). Wilczek showed that composite objects made of a nonrelativistic particle of charge q bound to a magnetic flux of (magnetic) charge Φ behaves as an object with fractional angular momentum $q\Phi/2\pi$. Here Φ is measured in units of the flux quantum 2π (in units in which $\hbar = c = e = 1$). Furthermore, in a subsequent paper, Wilczek (1982b) showed that, upon an adiabatic process in which the two composites exchange positions without their worldlines coinciding, the wave function of two identical flux-charge composites changes by a phase factor $\exp(\pm iq\Phi)$. For instance if $\Phi = \pi$ (i.e., a half-flux quantum), the acquired phase is equal to $\exp(i\pi) = -1$. Thus if the particle was a boson, the composite becomes a fermion and vice versa. Wilczek coined the term *anyon* to describe the behavior of an arbitrary charge-flux composite. Furthermore, this construction also implies that not only *fractional statistics* but also *fractional spin*, consistent with a generalization of the Spin-Statistics Theorem. In other terms, “flux-attachment” implies fractional statistics (and fractional spin). Clearly Wilczek’s construction gave an explicit physical grounding to the general arguments of the 1977 paper by Leinaas and Myrheim. It is worth to note the close analogy between this construction in 2+1 dimensions and the Wu-Yang construction in 3+1 dimensions [whose consistency with the Spin-Statistics Theorem had been shown earlier on by Goldhaber (1976)].

In this description, the statistics of the composites (the anyons) enters in the form of complex weights (phases) given in terms of the *linking numbers* of the worldlines. Hence, the concept of fractional statistics is intimately related to the theory of knots and of the representations of the braid group. These concepts were originally introduced in physics to describe statistical transmutation in the theory of solitons (Finkelstein and Rubinstein, 1968) in the context of the Skyrme model (Skyrme, 1962). Wu (1984) developed an

explicit connection between the work of Leinaas and Myrheim and Wilczek's work on anyons in terms of operations acting on the worldlines of the anyons and described by the Braid Group. Wu's work and the somewhat early paper by Wilczek and Zee on the statistics of solitons (Wilczek and Zee, 1983) marked the definite entry of the theory of knots (and of the braid group) in physics in general and in condensed matter physics in particular. The classification of anyons in terms of representations of the braid group labeled by the fractional statistics (determined by linking numbers) as well as of fractional (or topological) spin (determined by the writhing number of the worldlines) leads to a rich set of physical consequences. As it will turn out, Wilczek's anyons are described one-dimensional representations of the braid group. As we will see below, additional and intriguing (non-Abelian) representations will also play a role.

What is a topological field theory

We will now consider a special class of gauge theories known as topological field theories. These theories often (but not always) arise as the low energy limit of more complex gauge theories. In general, one expects that at low energies the phase of a gauge theory be either confining or deconfined. While confining phases have (from really good reasons!) attracted much attention, deconfined phases are often regarded as trivial, in the sense that the general expectation is that their vacuum states be unique and the spectrum of low lying states is either massive or massless.

Let us consider a gauge theory whose action on a manifold $\mathcal{M}$ with metric tensor $g_{\mu\nu}(x)$ is

$$S = \int_{\mathcal{M}} d^D x \sqrt{g} \mathcal{L}(g, A_\mu). \quad (221)$$

At the classical level, the energy-momentum tensor $T^{\mu\nu}(x)$ is the linear response of the action to an infinitesimal change of the local metric,

$$T^{\mu\nu}(x) \equiv \frac{\delta S}{\delta g_{\mu\nu}(x)}. \quad (222)$$

That a theory is topological means that depends only on the topology of the space in which is defined and, consequently, it is independent of the local properties that depend on the metric, for example, distances, angles. Therefore, at least at the classical level, the energy-momentum tensor of a topological field theory must vanish identically,

$$T^{\mu\nu} = 0. \quad (223)$$

In particular, if the theory is topological, the *energy* (or Hamiltonian) is also zero. Furthermore, if the theory is independent of the metric, it is invariant under *arbitrary* coordinate transformations. Thus, if the theory is a gauge theory, the expectation values of Wilson loops will be independent of the size and shape of the loops. Whether or not a theory of this type can be consistently defined at the quantum level is a subtle problem which we will briefly touch on below.

It turns out that, due to the nonlocal nature of the observables of a gauge theory, the low-energy regime of a theory in its deconfined phase can have nontrivial global properties. In what follows, we will say that a gauge theory is topological if all local excitations are massive (and in fact we will send their mass gaps to infinity). The remaining Hilbert space of states is determined by global properties of the theory, including the topology of the manifold of their space-time. In several cases, the effective action of a topological field theory does not depend on the metric of the space-time, at least at the classical level. In all cases, the observables are nonlocal objects, Wilson loops and their generalization.

Chern-Simons gauge theory

Gauge theories play a key role in physics. In 2+1 dimensions, it is possible to define a special gauge theory which is odd under time-reversal invariance and parity: Chern-Simons gauge theory. Originally introduced in Quantum Field Theory in 1982 by Deser et al. (1982a,b), Chern-Simons gauge theory can be defined for any compact Lie group, as well as an extension of Einstein's gravity in 2+1 dimensions. In 1989, Witten (1989) showed that Chern-Simons gauge theory computes the expectation values of configurations of Wilson loops, regarded as the worldlines of heavy particles, in terms of a set of topological invariants known as the Jones polynomial that classify knots in three dimensions.

We will consider the simplest case, the $U(1)$ Chern-Simons gauge theory. The Chern-Simons action for a $U(1)$ gauge field A_μ in 2+1 dimension is

$$S[A] = \frac{k}{4\pi} \int_{\Omega} d^3 x \epsilon_{\mu\nu\lambda} A^\mu \partial^\nu A^\lambda + \int_{\Omega} d^3 x J_\mu A^\mu \quad (224)$$

where J_μ is a set of conserved currents (representing the worldlines of a set of heavy particles). On a closed 3-manifold Ω (e.g., a sphere, a torus) the Chern-Simons action is gauge invariant provided the parameter k (known as the level) is an integer. If the manifold Ω has a boundary, the action is not gauge invariant at the boundary. Gauge invariance is restored by additional boundary degrees of freedom. This structure is general, and not just a feature of the $U(1)$ theory.

Since the Chern–Simons action is first order in derivatives, it is not invariant under time reversal and under parity (which in 2+1 dimensions is a reflection). These symmetries make this theory relevant to the description of the fractional quantum Hall effect. In the absence of external sources, $J_\mu = 0$, at the classical level the Chern–Simons action is invariant under arbitrary changes of coordinates. This means that the theory is, at least classically, a topological field theory.

For a general non-Abelian gauge group G , the Chern–Simons action becomes

$$S = \frac{k}{4\pi} \int_{\mathcal{M}} d^3x \operatorname{tr} \left(AdA + \frac{2}{3} A \wedge A \wedge A \right). \quad (225)$$

Here, the cubic term is shorthand for

$$\operatorname{tr}(A \wedge A \wedge A) \equiv \operatorname{tr}(\epsilon_{\mu\nu\lambda} A^\mu A^\nu A^\lambda) \quad (226)$$

for a gauge field A^μ that takes values on the algebra of the gauge group G .

BF gauge theory

A closely related (abelian) gauge theory is the so-called *BF* theory (Horowitz, 1989) which, in a general spacetime dimension D (even or odd), is a theory of a vector field A^μ (a one-form) and an antisymmetric tensor field B with $D - 2$ Lorentz indices (a $D2$ form), known as a Kalb–Ramond field. In 2+1 dimensions, the action of the BF theory is

$$S = \frac{k}{2\pi} \int_{\mathcal{M}} d^3x \epsilon_{\mu\nu\lambda} B^\lambda \partial^\mu A^\nu \quad (227)$$

where, once again, k is an integer.

The BF gauge theory has the same content as the topological sector of a discrete $\mathbb{Z}_k$ gauge theory. To see this, we will consider the theory of compact electrodynamics which is a $U(1)$ gauge theory minimally coupled to charged scalar field ϕ . We will assume that the gauge theory is defined for a compact $U(1)$ gauge group (meaning that the gauge flux is quantized) and that the complex scalar field has charge integer $k \in \mathbb{Z}$. As usual minimal coupling is implemented by introducing the covariant derivative $D_\mu = \partial_\mu + ikA_\mu$, where A_μ is the $U(1)$ gauge field. Deep in the phase in which the global $U(1)$ symmetry is spontaneously broken, usually called the Higgs regime, the amplitude of the scalar field is frozen at its (real) vacuum expectation value ϕ_0 but its phase ω , representing the Goldstone mode, is unconstrained. In this limit, the Lagrangian of this theory becomes

$$\mathcal{L} = |\phi_0|^2 (\partial_\mu \omega - kA_\mu)^2 - \frac{1}{4e^2} F_{\mu\nu}^2 \quad (228)$$

where e is the coupling constant of the gauge field (the electric charge) and $F_{\mu\nu}$ is the field strength of the gauge field A_μ . In general spacetime dimension D the charge e has units of $\text{length}^{(D-4)/2}$. In this limit the gauge field becomes massive (this is the Higgs mechanism). This theory has fluxes quantized in units of $2\pi/k$ and has only k distinct fluxes. This is the $\mathbb{Z}_k$ gauge theory.

Here we will consider this theory in 2+1 dimensions. We will use a Gaussian (Hubbard–Stratonovich) decoupling of the first term of Eq. (228) in terms of a gauge field C_μ to write the Lagrangian in the equivalent form

$$\mathcal{L} = -\frac{1}{4|\phi_0|^2} C_\mu^2 + C^\mu (\partial_\mu \omega - kA_\mu) - \frac{1}{4e^2} F_{\mu\nu}^2. \quad (229)$$

Up to an integration by parts, we see that the phase field ω plays the role of a Lagrange multiplier field, which forces the vector field B_μ to obey the constraint $\partial_\mu C^\mu = 0$. This constraint is solved by writing C_μ as

$$C_\mu = \frac{1}{2\pi} \epsilon_{\mu\nu\lambda} \partial^\nu B^\lambda \quad (230)$$

of a 1-form gauge field B_μ . Upon solving the constraint, the Lagrangian of Eq. (229) becomes

$$\mathcal{L} = \frac{k}{2\pi} \epsilon_{\mu\nu\lambda} A^\mu \partial^\nu B^\lambda - \frac{1}{4e^2} F_{\mu\nu}(A)^2 - \frac{1}{32\pi^2 |\phi_0|^2} F_{\mu\nu}(B)^2. \quad (231)$$

For spacetime dimensions $D < 4$ the IR the Maxwell terms for the fields A^μ and B_μ are irrelevant in the IR and, in this limit, this theory reduces to the BF theory at level k of Eq. (227). Therefore, $\mathbb{Z}_k$ gauge theory is equivalent to the BF theory at level k . In fact, this result is essentially valid in all dimensions with the main difference being that the field B_μ is, in general, a rank $D - 2$ Kalb–Ramond antisymmetric field.

Quantization of Abelian Chern–Simons gauge theory

By expanding the action of Eq. (224), the Lagrangian density becomes

$$\mathcal{L} = \frac{k}{4\pi} \epsilon_{ij} A_i \partial_0 A_j + A_0 \left(\frac{k}{2\pi} B - J_0 \right) - J_i A_i \quad (232)$$

where $B = \epsilon_{ij}\partial_i A_j$ is the local flux, J_0 is a local classical density, and J_i is a local classical current. Then, the first term of Eq. (232) implies that the spatial components of the gauge field obey equal-time canonical commutation relations

$$[A_1(x), A_2(x')] = i \frac{2\pi}{k} \delta(x - x'). \quad (233)$$

The second term of the Lagrangian enforces the Gauss Law which for this theory simply implies that the states in the physical Hilbert space obey the constraint

$$B(x) = \frac{2\pi}{k} J_0(x). \quad (234)$$

Thus the Gauss's Law requires that a charge density necessarily has a magnetic flux attached to it. In other terms, the physical states are charge-flux composites as postulated in Wilczek's theory (Wilczek, 1982b). This is the theoretical basis to the concept of flux attachment which, as we will see in Section "Chern–Simons gauge theory and the fractional quantum Hall effect," is widely used in the theory of the fractional quantum Hall effect.

The third term in Eq. (232) simply states that the Hamiltonian density is just

$$\mathcal{H} = J_i A_i \quad (235)$$

Hence, in the absence of sources, the Hamiltonian vanishes, $\mathcal{H} = 0$.

The Chern–Simons action is locally gauge-invariant, up to boundary terms. To see this, let us perform a gauge transformation, $A_\mu \rightarrow A_\mu + \partial_\mu \Phi$, where $\Phi(x)$ is a smooth, twice differentiable function. Then,

$$\begin{aligned} S[A^\mu + \partial^\mu \Phi] &= \int_{\mathcal{M}} (A^\mu + \partial^\mu \Phi) \epsilon_{\mu\nu\lambda} \partial^\nu (A^\lambda + \partial^\lambda \Phi) \\ &= \int_{\mathcal{M}} d^3x \epsilon_{\mu\nu\lambda} A^\mu \partial^\nu A^\lambda + \int_{\mathcal{M}} d^3x \epsilon_{\mu\nu\lambda} \partial^\mu \Phi \partial^\nu A^\lambda \end{aligned} \quad (236)$$

Therefore, the change is

$$S[A^\mu + \partial^\mu \Phi] - S[A^\mu] = \int_{\mathcal{M}} d^3x \partial^\mu \Phi F_\mu^* = \int_{\mathcal{M}} d^3x \partial^\mu (\Phi F_\mu^*) - \int_{\mathcal{M}} d^3x \Phi \partial^\mu F_\mu^* \quad (237)$$

where $F_\mu^* = \epsilon^{\mu\nu\lambda} \partial_\nu A_\lambda$ is the dual field strength. However, in the absence of magnetic monopoles, this field satisfies the Bianchi identity, $\partial^\mu F_\mu^* = \partial^\mu (\epsilon_{\mu\nu\lambda} \partial^\nu A^\lambda) = 0$. Therefore, using the Gauss Theorem, we find that the change of the action is a total derivative and integrates to the boundary

$$\delta S = \int_{\mathcal{M}} d^3x \partial^\mu (\Phi F_\mu^*) = \int_{\Sigma} dS^\mu \Phi F_\mu^* \quad (238)$$

where $\Sigma = \partial\mathcal{M}$ is the boundary of $\mathcal{M}$. In particular, if Φ is a nonzero constant function on $\mathcal{M}$, then the change of the action under such a gauge transformation is

$$\delta S = \Phi \times \text{flux}(\Sigma). \quad (239)$$

Hence, the action is not invariant if the manifold has a boundary, and the theory must be supplied with additional degrees of freedom at the boundary.

Indeed, the flat connections, that is, the solution of the equations of motion, $F_{\mu\nu} = 0$, are pure gauge transformations, $A_\mu = \partial_\mu \phi$, and have an action that integrates to the boundary. Let $\mathcal{M} = D \times \mathbb{R}$ where D is a disk in space and $\mathbb{R}$ is time. The boundary manifold is $\Sigma = S^1 \times \mathbb{R}$, where S^1 is a circle. Thus, in this case, the boundary manifold Σ is isomorphic to a cylinder. The action of the flat configurations reduces to

$$S = \int_{S^1 \times \mathbb{R}} d^2x \frac{k}{4\pi} \partial_0 \phi \partial_1 \phi \quad (240)$$

This implies that the dynamics on the boundary is that of a scalar field on a circle S^1 , and obeys periodic boundary conditions.

Although classically the theory does not depend on the metric, it is invariant under arbitrary transformations of the coordinates. However, any gauge fixing condition will automatically break this large symmetry. For instance, we can specify a gauge condition at the boundary in the form of a boundary term of the form $\mathcal{L}_{\text{gauge fixing}} = A_1^2$. In this case, the boundary action of the field φ becomes

$$S[\varphi] = \int_{S^1 \times \mathbb{R}} d^2x \frac{k}{4\pi} [\partial_0 \phi \partial_1 \phi - (\partial_1 \phi)^2]. \quad (241)$$

The solutions of the equations of motion of this compactified scalar field have the form $\phi(x_1 \mp x_0)$, and are right (left) moving chiral fields depending of the sign of k . This boundary theory is not topological but is conformally invariant.

A similar result is found in non-Abelian Chern–Simons gauge theory. In the case of the $SU(N)_k$ Chern–Simons theory on a manifold $D \times \mathbb{R}$, where D is a disk whose boundary is Γ , and $\mathbb{R}$ is time, the action is

$$S_{\text{CS}}[A] = \int_{D \times \mathbb{R}} d^3x \left[\frac{k}{8\pi} \text{tr} \left(\epsilon_{\mu\nu\lambda} A^\mu \partial^\nu A^\lambda + \frac{2}{3} \epsilon^{\mu\nu\lambda} A_\mu A_\nu A_\lambda \right) \right]. \quad (242)$$

This theory integrates to the boundary, $\Gamma \times \mathbb{R}$ where it becomes the chiral (right-moving) $SU(N)_k$ Wess–Zumino–Witten model (at level k) at its IR fixed point, $\lambda_c^2 = 4\pi/k$

$$S_{\text{WZW}}[g] = \frac{1}{4\lambda_c^2} \int_{\Gamma \times \mathbb{R}} d^2x \text{tr}(\partial_\mu g \partial^\mu g^{-1}) + \frac{k}{12\pi} \int_B \epsilon^{\mu\nu\lambda} \text{tr}(g^{-1} \partial_\mu g g^{-1} \partial_\nu g g^{-1} \partial_\lambda g). \quad (243)$$

Here, $g \in SU(N)$ parametrizes the flat configurations of the Chern–Simons gauge theory. The boundary theory is a nontrivial CFT, the chiral Wess–Zumino–Witten CFT (Witten, 1989).

Vacuum degeneracy a torus

We will now construct the quantum version of the $U(1)$ Chern–Simons gauge theory on a manifold $\mathcal{M} = T^2 \times \mathbb{R}$, where T^2 is a spatial torus, of linear size L_1 and L_2 . Since this manifold does not have boundaries, the flat connections, $\epsilon_{ij} \partial_i A_j = 0$, do not reduce to local gauge transformations of the form $A_i = \partial_i \Phi$. Indeed, the holonomies of the torus T^2 , that is, the Wilson loops on the two noncontractible cycles of the torus Γ_1 and Γ_2 , are gauge-invariant observables:

$$\int_0^{L_1} dx_1 A_1 \equiv \bar{a}_1, \quad \int_0^{L_2} dx_2 A_2 \equiv \bar{a}_2 \quad (244)$$

where $\bar{a}_1$ and $\bar{a}_2$ are time-dependent. Thus, the flat connections now are

$$A_1 = \partial_1 \Phi + \frac{\bar{a}_1}{L_1}, \quad A_2 = \partial_2 \Phi + \frac{\bar{a}_2}{L_2} \quad (245)$$

whose action is

$$S = \frac{k}{4\pi} \int dx_0 \epsilon_{ij} \bar{a}_i \partial_0 \bar{a}_j \quad (246)$$

Therefore, the global degrees of freedom $\bar{a}_1$ and $\bar{a}_2$ at the quantum level become operators that satisfy the commutation relations

$$[\bar{a}_1, \bar{a}_2] = i \frac{2\pi}{k}. \quad (247)$$

We find that the flat connections are described by the quantum mechanics of $\bar{a}_1$ and $\bar{a}_2$. A representation of this algebra is

$$\bar{a}_2 \equiv -i \frac{2\pi}{k} \frac{\partial}{\partial \bar{a}_1}. \quad (248)$$

Furthermore, the Wilson loops on the two cycles become

$$W[\Gamma_1] = \exp \left(i \int_0^{L_1} A_1 \right) \equiv e^{i\bar{a}_1}, \quad W[\Gamma_2] = \exp \left(i \int_0^{L_2} A_2 \right) \equiv e^{i\bar{a}_2} \quad (249)$$

and satisfy the algebra

$$W[\Gamma_1] W[\Gamma_2] = \exp(-i2\pi/k) W[\Gamma_2] W[\Gamma_1]. \quad (250)$$

Under large gauge transformations

$$\bar{a}_1 \rightarrow \bar{a}_1 + 2\pi, \quad \bar{a}_2 \rightarrow \bar{a}_2 + 2\pi. \quad (251)$$

Therefore, invariance under large gauge transformations on the torus implies that $\bar{a}_1$ and $\bar{a}_2$ define a two-torus target space.

Let us define the unitary operators

$$U_1 = \exp(ik\bar{a}_2), \quad U_2 = \exp(-ik\bar{a}_1) \quad (252)$$

which satisfy the algebra

$$U_1 U_2 = \exp(i2\pi k) U_2 U_1. \quad (253)$$

The unitary transformations U_1 and U_2 act as shift operators on $\bar{a}_1$ and $\bar{a}_2$ by 2π , and hence generate the large gauge transformations. Moreover, the unitary operators U_1 and U_2 leave the Wilson loop operators on noncontractible cycles invariant,

$$U_1^{-1} W[\Gamma_1] U_1 = W[\Gamma_1], \quad U_2^{-1} W[\Gamma_2] U_2 = W[\Gamma_2]. \quad (254)$$

Let $|0\rangle$ be the eigenstate of $W[\Gamma_1]$ with eigenvalue 1, that is, $W[\Gamma_1]|0\rangle = |0\rangle$. The state $W[\Gamma_2]|0\rangle$ is also an eigenstate of $W[\Gamma_1]$ with eigenvalue $\exp(-i2\pi/k)$, since

$$W[\Gamma_1]W[\Gamma_2]|0\rangle = e^{i2\pi/k}W[\Gamma_2]W[\Gamma_1]|0\rangle = e^{-i2\pi/k}W[\gamma_2]|0\rangle. \quad (255)$$

More generally, since

$$W[\Gamma_1]W^p[\Gamma_2]||0\rangle = e^{-i2\pi p/k}W^p[\Gamma_2]|0\rangle \quad (256)$$

we find that, provided $k \in \mathbb{Z}$, there are k linearly independent vacuum states $|p\rangle = W^p[\Gamma_2]|0\rangle$, for the $U(1)$ Chern–Simons gauge theory at level k . It is denoted as the $U(1)_k$ Chern–Simons theory. Therefore the finite-dimensional topological space on a two-torus is k -dimensional. It is trivial to show that, on a surface of genus g , the degeneracy is k^g .

We see that in the Abelian $U(1)_k$ Chern–Simons theory, the Wilson loops must carry k possible values of the unit charge. This property generalizes to the non-Abelian theories, which are technically more subtle. We will only state some important results. For example, if the gauge group is $SU(2)$, we expect that the Wilson loops will carry the representation labels of the group $SU(2)$, that is, they will be labeled by (j, m) , where $j = 0, \frac{1}{2}, 1, \dots$ and the $2j + 1$ values of m satisfy $|m| \leq j$. However, it turns out that out $SU(2)_k$ Chern–Simons theory has fewer states, and that the values of j are restricted to the range $j = 0, \frac{1}{2}, \dots, \frac{k}{2}$.

Fractional statistics and braids

Another aspect of the topological nature of Chern–Simons theory is the behavior of expectation values of products of Wilson loop operators. Let us compute the expectation value of a product of two Wilson loop operators on two positively oriented closed contours γ_1 and γ_2 . We will do this computation in the Abelian Chern–Simons theory $U(1)_k$ in 2+1-dimensional Euclidean space. Note that the Euclidean Chern–Simons action is pure imaginary since the action is first order in derivatives. The expectation value to be computed is

$$W[\gamma_1 \cup \gamma_2] = \left\langle \exp \left(i \oint_{\gamma_1 \cup \gamma_2} dx_\mu A_\mu \right) \right\rangle_{\text{CS}}. \quad (257)$$

The result changes depending on whether the loops γ_1 and γ_2 are linked or unlinked. In this section, we will compute the contribution to this expression for a pair of contours γ_1 and γ_2 . Here we will not include the contribution to this expectation value for each contours. We will return to this problem in Section “Bosonization of the Dirac theory in 2+1 dimensions” where we discuss the problem of fractional spin.

The expectation value of a Wilson loop on the union of two contours, as in the present case, γ can be written as

$$\left\langle \exp \left(i \oint_\gamma dx_\mu A_\mu \right) \right\rangle_{\text{CS}} = \left\langle \exp \left(i \int d^3x J_\mu A_\mu \right) \right\rangle_{\text{CS}} \quad (258)$$

where the current J_μ is

$$J_\mu(x) = \delta(x_\mu - z_\mu(t)) \frac{dz_\mu}{dt} \quad (259)$$

Here, $z_\mu(t)$ is a parametrization of the contour γ . Therefore, the expectation value of the Wilson loop is (Witten, 1989)

$$\left\langle \exp \left(i \oint_\gamma dx_\mu A_\mu \right) \right\rangle_{\text{CS}} \equiv \exp(iI[\gamma]_{\text{CS}}) = \exp \left(-\frac{i}{2} \int d^3x \int d^3y J_\mu(x) G_{\mu\nu}(x - y) J_\nu(y) \right) \quad (260)$$

where $G_{\mu\nu}(x - y) = \langle A_\mu(x) A_\nu(y) \rangle_{\text{CS}}$ is the propagator of the Chern–Simons gauge field. Since the loops are closed, the current J_μ is conserved, that is, $\partial_\mu J_\mu = 0$, and the effective action $I[\gamma]_{\text{CS}}$ of the loop γ is gauge-invariant.

The Euclidean propagator of Chern–Simons gauge theory (in the Feynman gauge) is

$$G_{\mu\nu}(x - y) = \frac{2\pi}{k} G_0(x - y) \epsilon_{\mu\nu\lambda} \partial_\lambda \delta(x - y) \quad (261)$$

where $G_0(x - y)$ is the propagator of the massless Euclidean scalar field, which satisfies

$$-\partial^2 G_0(x - y) = \delta^3(x - y). \quad (262)$$

Using these results, we find the following expression for the effective action

$$\begin{aligned} I[\gamma]_{\text{CS}} &= \frac{\pi}{k} \int d^3x \int d^3y J_\mu(x) J_\nu(y) G_0(x - y) \epsilon_{\mu\nu\lambda} \partial_\lambda \delta(x - y) \\ &= \frac{\pi}{k} \oint_\gamma dx_\mu \oint_\gamma dy_\nu \epsilon_{\mu\nu\lambda} \partial_\lambda G_0(x - y). \end{aligned} \quad (263)$$

Since the current J_μ is conserved, it can be written as the curl of a vector field, B_μ , as

$$J_\mu = \epsilon_{\mu\nu\lambda} \partial_\nu B_\lambda. \quad (264)$$

In the Lorentz gauge, $\partial_\mu B_\mu = 0$, we can write

$$B_\mu = \epsilon_{\mu\nu\lambda} \partial_\nu \phi_\lambda. \quad (265)$$

Hence,

$$J_\mu = -\partial^2 \phi_\mu \quad (266)$$

where

$$\phi_\mu(x) = \int d^3\gamma G_0(x - \gamma) J_\mu(\gamma) \quad (267)$$

Upon substituting this result into the expression for B_μ , we find

$$B_\mu = \int d^3\gamma \epsilon_{\mu\nu\lambda} \partial_\nu G_0(x - \gamma) J_\lambda(\gamma) = \oint_\gamma \epsilon_{\mu\nu\lambda} \partial_\nu G_0(x - \gamma) d\gamma_\lambda. \quad (268)$$

Therefore, the effective action $I[\gamma]_{\text{CS}}$ becomes

$$I[\gamma]_{\text{CS}} = \frac{\pi}{k} \oint_\gamma dx_\mu \oint_\gamma d\gamma_\nu \epsilon_{\mu\nu\lambda} \partial_\lambda G_0(x - \gamma) = \frac{\pi}{k} \oint_\gamma dx_\mu B_\mu(x). \quad (269)$$

Let Σ be an oriented open surface of the Euclidean three-dimensional space whose boundary is the oriented loop (or union of loops) γ , that is, $\partial\Sigma = \gamma$. Then, using Stokes Theorem we write in the last line of Eq. (269) as

$$I[\gamma]_{\text{CS}} = \frac{\pi}{k} \int_\Sigma dS_\mu \epsilon_{\mu\nu\lambda} \partial_\nu B_\lambda = \frac{\pi}{k} \int_\Sigma dS_\mu J_\mu. \quad (270)$$

The integral in the last line of this equation is the flux of the current J_μ through the surface Σ . Therefore, this integral counts the number of times n_γ the Wilson loop on γ pierces the surface Σ (whose boundary is γ), and therefore it is an integer, $n_\gamma \in \mathbb{Z}$. We will call this integer the *linking number* (or Gauss invariant) of the configuration of loops. In other words, the expectation value of the Wilson loop operator is

$$W[\gamma]_{\text{CS}} = e^{i\pi n_\gamma/k}. \quad (271)$$

The linking number is a *topological invariant* since, being an integer, its value cannot be changed by smooth deformations of the loops, provided they are not allowed to cross.

We will now see that this property of Wilson loops in Chern–Simons gauge theory leads to the concept of fractional statistics. Let us consider a scalar matter field that is massive and charged under the Chern–Simons gauge field. The excitations of this matter field are particles that couple minimally to the gauge field. Here we will be interested in the case in which these particles are very heavy. In that limit, we can focus on states that have a few of these particles which will be in their nonrelativistic regime.

Consider, for example, a state with two particles which in the remote past, at time $t = -T \rightarrow -\infty$, are located at two points A and B . This initial state will evolve to a final state at time $t = T \rightarrow \infty$, in which the particles go back either to their initial locations (the direct process) or to another one in which they exchange places, $A \leftrightarrow B$. At intermediate times, the particles follow smooth worldlines. These are two processes, direct and exchange. There we see that the direct process is equivalent to a history with two unlinked loops (the worldlines of the particles), whereas in the exchange process, the two loops form a link. It follows from the preceding discussion that the two amplitudes differ by the result of the computation of the Wilson loop expectation value for the loops γ_1 and γ_2 . Let us call the first amplitude W_{direct} and the second W_{exchange} . The result is

$$W_{\text{exchange}} = W_{\text{direct}} e^{\pm i\pi/k} \quad (272)$$

where the sign depends on how the two worldlines wind around each other.

An equivalent interpretation of this result is that if $\Psi[A, B]$ is the wave function with the two particles at locations A and B , the wavefunction where their locations are exchanged is

$$\Psi[B, A] = e^{\pm i\pi/k} \Psi[A, B] \quad (273)$$

where the sign depends on whether the exchange is done counterclockwise or clockwise. Clearly, for $k = 1$, the wave function is antisymmetric and the particles are fermions, while for $k \rightarrow \infty$, they are bosons. At other values of k , the particles obey *fractional statistics* and are called *anyons* (Wilczek, 1982a; Leinaas and Myrheim, 1977). The phase factor $\phi = \pm\pi/k$ is called the statistical phase.

Notice that while for fermions and bosons the statistical phase $\varphi = 0, \pi$ is uniquely defined (mod 2π), for other values of k , the statistical angle is specified up to a sign that specifies how the worldlines wind around each other. Indeed, mathematically the exchange process is known as a *braid*. Processes in which the worldlines wind clock and counterclockwise are braids that are inverse of each other. Braids can also be stacked sequentially yielding multiples of the phase φ . In addition to stacking braids, Wilson loops can be fused: seen from some distance, a pair of particles will behave as a new particle with a well-defined behavior under braiding. This process of fusion is closely related to the concept of fusion of primary fields in CFT.

Furthermore, up to regularization subtleties (Grundberg et al., 1990), the self-linking terms (those with $a = b$) yield a topological spin $1/2k$, consistent with the spin-statistics connection (Polyakov, 1988). For $k = 1$, this means that the flux-charge composites have spin $1/2$.

What we have just described is a mathematical structure called the *Braid* group. The example that we worked out using Abelian Chern–Simons theory yields one-dimensional representations of the Braid group with the phase φ being the label of the representations. For $U(1)_k$, there are k types of particles (anyons). That these representations are Abelian means that, in the general case of $U(1)_k$, acting on a one-dimensional representation p (defined mod k) with a one-dimensional representation q (also defined mod k) yields the representation one-dimensional $p + q \pmod{k}$. We will denote the operation of *fusing* these representations (particles!) as $[q]_{\text{mod } k} \times [p]_{\text{mod } k} = [q+p]_{\text{mod } k}$. These representations are in one-to-one correspondence with the inequivalent charges of the Wilson loops, and with the vacuum degeneracy of the $U(1)_k$ Chern–Simons theory on a torus.

A richer structure arises in the case of the non-Abelian Chern–Simons theory at level k (Witten, 1989), such as $SU(2)_k$. For example, for $SU(2)_1$, the theory has only two representations, both are one-dimensional, and have statistical angles $\varphi = 0, \pi/2$.

However, for $SU(2)_k$, the content is more complex. In the case of $SU(2)_2$, the theory has (a) a trivial representation $[0]$ (the identity, $(j, m) = (0, 0)$), (b) a (spinor) representation $[1/2]$ ($(j, m) = (1/2, \pm 1/2)$), and (c) a the representation $[1]$ ($(j, m) = (1, m)$, with $m = 0, \pm 1$). These states will fuse obeying the following rules: $[0] \times [0] = [0]$, $[0] \times [1/2] = [1/2]$, $[0] \times [1] = [1]$, $[1/2] \times [1/2] = [0] + [1]$, $[1/2] \times [1] = [1/2]$, and $[1] \times [1] = [0]$ (note the truncation of the fusion process!).

Of particular interest is the case $[1/2] \times [1/2] = [0] + [1]$. In this case, we have two fusion channels, labeled by $[0]$ and $[1]$. The braiding operations now will act on a two-dimensional Hilbert space and are represented by 2×2 matrices. This is an example of a non-Abelian representation of the braid group. These rather abstract concepts have found a physical manifestation in the physics of the fractional quantum Hall fluids, whose excitations are vortices that carry fractional charge and anyon (braid) fractional statistics.

Why this is interesting can be seen by considering a Chern–Simons gauge theory with four quasi-static Wilson loops. For instance in the case of the $SU(2)_2$ Chern–Simons theory the Wilson loops carry the spinor representation, $[1/2]$. If we call the four particles A, B, C , and D , we would expect that their quantum state would be completely determined by the coordinates of the particles. This, however, is not the case since, if we fuse A with B , the result is either a state $[0]$ or a state $[1]$. Thus, if the particles were prepared originally in some state, braiding (and fusion) will lead to a linear superposition of the two states. This braiding process defines a unitary matrix, a representation of the Braid Group. The same is true with the other particles. However, it turns out that for four particles, there are only two linearly independent states. This twofold degenerate Hilbert space of topological origin is called a topological qubit.

Moreover, if we consider a system with N (even) number of such particles, the dimension of the topologically protected Hilbert space is $2^{N/2-1}$. Hence, for large N , the entropy per particle grows as $\frac{1}{2} \ln 2 = \ln \sqrt{2}$. Therefore the qubit is not an “internal” degree of freedom of the particles but a collective state of topological origin. Interestingly, there are physical systems, known as non-Abelian fractional quantum Hall fluids that embody this physics and are accessible to experiments! For these reasons, the non-Abelian case has been proposed as a realization of a topological qubit (Kitaev, 2003; Das Sarma et al., 2008).

Topological phases of matter

Topological insulators

We will now give a brief discussion of the physics of Topological Insulators from a field-theoretic perspective. Topological insulators are systems whose electronic states (band structures) have special topological properties that manifest in the existence of symmetry-protected edge states. For this reason these systems are known as symmetry-protected topological states (or SPTs). The simplest example is found in one space dimension where it is related to the fascinating problem of fractionally charged solitons and electron fractionalization. In several ways many of the concepts involved in these 1+1-dimensional systems can and have been extended to higher dimensions.

Dirac fermions in 2+1 dimensions

We will now see that, in spite of the formal similarities with the 1+1 dimensional case, this theory has different symmetries, particularly concerning parity and time-reversal invariance. In addition, in 2+1 dimensions, it is not possible to define a γ^5 Dirac matrix, which implies that there is no chiral symmetry and no chiral anomaly. We will consider first a theory of a Dirac field which in 2+1 dimensions is a bi-spinor (as is in 1+1 dimensions). The Lagrangian of the Dirac theory coupled to a background gauge field A_μ is

$$\mathcal{L} = \bar{\psi} i \gamma^\mu \partial_\mu \psi - m \bar{\psi} \psi - e A_\mu \bar{\psi} \gamma^\mu \psi \equiv \bar{\psi} i \gamma^\mu D_\mu(A) \psi - m \bar{\psi} \psi \quad (274)$$

where $\bar{\psi} = \psi^\dagger \gamma_0$, $\bar{\psi} \gamma_\mu \psi \equiv j_\mu$ is the gauge-invariant (and conserved) Dirac current, and $D_\mu(A) = \partial_\mu + ie A_\mu$ is the covariant derivative.

In Eq. (274), γ_μ are the three 2×2 Dirac matrices which obey the algebra, $\{\gamma_\mu, \gamma_\nu\} = 2g_{\mu\nu}$, where $g_{\mu\nu} = \text{diag}(1, -1, -1)$ is the metric of 2+1 dimensional Minkowski spacetime. The Dirac matrices γ_μ can be written in terms of the three 2×2 Pauli matrices. For instance we can choose $\gamma_0 = \sigma_3$, $\gamma_1 = i\sigma_2$ and $\gamma_2 = -i\sigma_1$, which satisfy the Dirac algebra. Since the three gamma matrices involve all three Pauli matrices, it is not possible to define a γ_5 matrix, which would anticommute with the gamma matrices. In this sense, it is not possible to define a chirality for bi-spinors in 2+1 dimensions

We could have also chosen a different set of gamma matrices. For instance, we could have chosen $\gamma_0 = \sigma_3$, $\gamma_1 = i\sigma_2$, and $\gamma_2 = +i\sigma_1$, which also satisfy the Dirac algebra. These two choices are equivalent to the 2D parity transformation $x_1 \rightarrow x_1$ and $x_2 \rightarrow -x_2$. In other words, we can choose the three gamma matrices to be defined in terms of a right-handed or a left-handed frame (or triad). Thus, the choice of handedness of the frame used to define the gamma matrices can be regarded as a chirality.

The parity transformation is also equivalent to a unitary transformation (a change of basis) $U = \gamma_1 = i\sigma_1$ which flips the sign of both γ_2 and γ_0 . Thus, a parity transformation is equivalent to a change of the sign of γ_0 or, what is the same, as changing the *sign* of the Dirac mass $m \rightarrow -m$. Since the Dirac theory is charge conjugation invariant, the parity transformation is equivalent to time reversal. It is easy to see that in 2+1 dimensions, the massive Dirac theory is not invariant under time reversal since the single particle Dirac Hamiltonian $H(\mathbf{p})$ for momentum $\mathbf{p}$ involves all three Pauli matrices,

$$H(\mathbf{p}) = \boldsymbol{\alpha} \cdot \mathbf{p} + \beta m \quad (275)$$

where, as usual, $\boldsymbol{\alpha} = \gamma_0 \boldsymbol{\gamma}$ and $\beta = \gamma_0$. In fact, time reversal is equivalent to the change of the sign of the Dirac mass. These considerations also apply to the massless Dirac theory coupled to a background gauge field.

Dirac fermions and topological insulators

In addition systems in one space dimension, discussed in Section “Dirac fermions in one space dimensions,” in which Dirac fermions naturally describe the low energy electronic degrees of freedom, Dirac fermions also play a role in many other systems in condensed matter physics. Such systems range from the nodal Bogoliubov fermionic excitations of d-wave superconductors in 2D and p-wave superfluids in 3D, to Chern and $\mathbb{Z}_2$ topological insulators in 2D and $\mathbb{Z}_2$ topological insulators and Weyl semimetals in 3D. They also play a role in spin liquid phases of frustrated spin-1/2 quantum antiferromagnets, such as Dirac and chiral spin liquids. Dirac fermions also play a significant role in our understanding of the compressible limit of 2D electron gases (2DEG) in large magnetic fields (see Section “Chern–Simons gauge theory and the fractional quantum Hall effect”). We will not cover here all of these examples. Instead we will focus on the 2D Chern topological insulators (which exhibit the anomalous quantum Hall effect) and on the 3D $\mathbb{Z}_2$ topological insulators.

In condensed matter physics the important low energy electronic degrees of freedom belong to the electronic states close to the Fermi energy. In such systems, the lattice periodic potential determines the properties of their band structures. The only significant exception to this general rule is the case of the 2DEGs in GaAs-AlAs heterostructures (the most commonly used platform for the study of quantum hall effects) whose electronic densities are low enough so that the lattice periodic potential can for practical purposes almost always be ignored.

In general, Dirac (and Weyl) fermions arise when the conduction and valence bands cross at isolated points of the Brillouin zone. In such situations, the near the crossing points the low energy electronic states locally (in momentum space) look like cones and, ignoring possible anisotropies, look like the states of a Dirac-Weyl theory. For these reasons, Dirac fermions play a central role in the theory of graphene type materials (Castro Neto et al., 2009) and, more significantly, in the theory of topological insulators (Qi and Zhang, 2011).

Dirac fermions play a central role in Quantum Electrodynamics and in the Standard Model of Particle Physics. The problem of quark confinement requires an understanding of these theories in a regime inaccessible to Feynman-diagrammatic perturbation theory and an intrinsically nonperturbative formulation, known as Lattice Gauge Theory (Wilson, 1974; Kogut and Susskind, 1975; Susskind, 1977), needed to be developed. For this reason, in the 1970s, fermionic Hamiltonians with crossings at points became of great interest in High Energy Physics as a way to describing the short-distance dynamics of quarks in lattice gauge theory.

This program runs into difficulties when extended to the theory of Weak Interactions, which have an odd number of species of chiral (Weyl) Dirac fermions. All local discretizations of the Dirac equation yield an even number of species. This fact came to be known as the fermion doubling problem. These results are special cases of a general theorem, due to Nielsen and Ninomiya (1981a, b, 1983) [and extended by Friedan (1982)], which proves that for systems whose kinetic energy is *local* in space (as it must be) there must always be an *even* number of crossings. Therefore, it is impossible to write a local theory with an odd number of chiral fermionic species.

In the context of condensed matter physics, the simplest example of Dirac fermions is found in the electronic structure of graphene (a single layer of graphite) discussed by Castro Neto et al. (2009). Graphene is an allotrope of crystalline carbon in which the carbon atoms are arranged in a 2D hexagonal lattice, which is a lattice with two inequivalent sites in its unit cell, labeled by A and B . Let $\mathbf{r}_A$ and $\mathbf{r}_B$ be the sites of the two sublattices. Each site $\mathbf{r}_A$ has three nearest neighbors on the B sublattice located at $\mathbf{r}_B^i = \mathbf{r}_A + \mathbf{d}_i$, where $i = 1, 2, 3$ and

$$\mathbf{d}_1 = \left(\frac{1}{2\sqrt{3}}, \frac{1}{2} \right), \quad \mathbf{d}_2 = \left(\frac{1}{2\sqrt{3}}, -\frac{1}{2} \right), \quad \mathbf{d}_3 = \left(-\frac{1}{\sqrt{3}}, 0 \right) \quad (276)$$

(in units in which the lattice spacing is $a = 1$). The nearest neighbor A sites are related by the vectors

$$\mathbf{a}_1 = \left(\frac{\sqrt{3}}{2}, -\frac{1}{2} \right), \quad \mathbf{a}_2 = (0, 1), \quad \mathbf{a}_3 = \left(-\frac{\sqrt{3}}{2}, -\frac{1}{2} \right) \quad (277)$$

where $\mathbf{a}_1$ and $\mathbf{a}_2$ are the primitive lattice vector of the hexagonal lattice. The nearest neighbor sites of the B sublattice are also related by these same three vectors.

The low energy electronic degrees of freedom of graphene can be described by a single fermionic state (ignoring spin) at each carbon atom. Let $c^\dagger(r_A)$ and $c^\dagger(r_B)$ be the fermion operators that create an electron at the site r_A and at the site nearest neighbor sites r_B , respectively. The Hamiltonian is

$$H = t_1 \sum_{r_A, i=1,2,3} c^\dagger(r_A) c(r_A + d_i) + \text{h.c.} \quad (278)$$

where t_1 is the hopping matrix element between nearest neighbor A and B sites.

In Fourier space

$$c(r_A) = \int_{\text{BZ}} \frac{d^2 k}{(2\pi)^2} \psi_A(\mathbf{k}) \exp(i\mathbf{k} \cdot \mathbf{r}_A), \quad c(r_B) = \int_{\text{BZ}} \frac{d^2 k}{(2\pi)^2} \psi_B(\mathbf{k}) \exp(i\mathbf{k} \cdot \mathbf{r}_B) \quad (279)$$

where BZ is the first Brillouin zone of the hexagonal lattice, a hexagonal region of reciprocal space with vertices at $\pm 2\pi/\sqrt{3}(1, 1/\sqrt{3})$ (which are denoted by K and K' , respectively) and their two images under $2\pi/3$ rotations. In momentum space the Hamiltonian is (Semenoff, 1984)

$$H = t_1 \int_{\text{BZ}} \frac{d^2 k}{(2\pi)^2} (\psi_A(\mathbf{k}) \quad \psi_B(\mathbf{k})) \begin{pmatrix} 0 & \sum_{j=1,2,3} \exp(i\mathbf{k} \cdot \mathbf{d}_j) \\ \sum_{j=1,2,3} \exp(-i\mathbf{k} \cdot \mathbf{d}_j) & 0 \end{pmatrix} \begin{pmatrix} \psi_A(\mathbf{k}) \\ \psi_B(\mathbf{k}) \end{pmatrix} \quad (280)$$

The one-particle states of this Hamiltonian have eigenvalues $E(\mathbf{k}) = \pm |\sum_{j=1,2,3} \exp(i\mathbf{k} \cdot \mathbf{d}_j)|$. Clearly $E(\mathbf{k})$ vanishes at the K and K' points, the corners of the Brillouin zone. Hence, there is a crossing of the two bands at the K and K' points near which the energy eigenvalues are a two cones at K and K' , respectively. Thus, the low energy states of graphene consist of two massless (gapless) Dirac bi-spinors, with opposite chirality/parity.

Other examples with similar fermion content are a theory of fermions on a 2D square lattice with a π magnetic flux ($1/2$ of the flux quantum) per plaquette which arises, for instance, in the theory of the integer quantum Hall effect on lattices by Thouless et al. (1982) (albeit for more general flux per plaquette), and in the theory of flux phases of 2D spin liquids of Affleck and Marston (1988). It also arises in the theory of the chiral spin liquid of Wen et al. (1989). We will discuss these theories in Section “Topological phases of matter.”

Chern invariants

The single-particle quantum states of free fermions (electrons) in the periodic potential of a crystal are Bloch wave functions labeled by the lattice momentum $\mathbf{k}$ and band indices m . The Bloch states are periodic functions of the lattice momenta whose periods are the Brillouin zones. Topologically each Brillouin zone is a torus: in 1D is a 1-torus, in 2D a 2-torus, etc. The symmetries (and shapes) of the Brillouin zone are dictated by the symmetries of the host crystal.

In this section we will consider the quantum states of systems of fermions on a 2D lattice with M bands with eigenvalues $\{E_m(\mathbf{k})\}$ with $m = 1, \dots, M$. The eigenstates are Bloch states $\{|u_m(\mathbf{k})\rangle\}$ such that the wave functions are $\psi_m(\mathbf{x}) = u_m(\mathbf{k}) \exp(i\mathbf{k} \cdot \mathbf{x})$, where $\mathbf{k}$ is a (quasi) momentum in the first Brillouin zone (Bloch, 1929). We will assume that the band spectrum is such that all the bands are separated from each other by a finite gap for all momenta in the first Brillouin zone. Hence, the eigenvalues obey the inequality $|E_m(\mathbf{k}) - E_n(\mathbf{k})| > 0$. We will assume that the system of interest has $N < M$ filled bands and, consequently, that there is a gap separating the top-most occupied band N (the “valence band”) and the lowest unoccupied band $N + 1$ (the “conduction band”) that does not close everywhere in the first Brillouin zone.

Let us consider specifically a 2D system and a Bloch state $|u_m(\mathbf{k})\rangle$ at a momentum $\mathbf{k}$, and let $\partial_k |u_m(\mathbf{k})\rangle$ be an infinitesimally close Bloch state with momentum $\mathbf{k}' = \mathbf{k} + d\mathbf{k}$. The inner product of these two infinitesimally close Bloch states is the vector field (defined on the first Brillouin zone for each band m)

$$\mathcal{A}_j^{(m)}(\mathbf{k}) = i \langle u_m(\mathbf{k}) | \partial_j | u_m(\mathbf{k}) \rangle \quad (281)$$

where $j = 1, 2$ are the orthogonal directions in momentum space, and we have used the notation $\partial_i = \partial/\partial k_i$. This vector field is known as the *Berry Connection* of the electronic states in the m th band.

The theory of the quantum states of noninteracting electrons in periodic potentials as developed by Bloch (1929) is the foundation of much of what we know about the physics of many semiconductors and simple metals. This theory is the core subject of many textbooks (Kittel, 1996; Ashcroft and Mermin, 1976). This theory is based on the classification of the electronic states as representations of the group of lattice translations and point (and spatial) group symmetry transformations. A key unstated assumption in much of this body of work is that the Bloch states are globally well-defined functions on the Brillouin zone of a given crystal. It is rather remarkable that this assumption was not stated explicitly since the original work by Bloch in 1929 until the work by Thouless, Kohmoto, Nightingale and den Nijs on the quantum states of electrons on 2D lattices in the presence of an uniform magnetic field (Thouless et al., 1982). The realization that there is a topological obstruction to define the electronic states globally in the Brillouin zone is the key to the development of the theory of topological insulators and, more generally, of the modern theory of band structures (Bradlyn et al., 2017; Cano and Bradlyn, 2021).

In quantum mechanics, states are defined up to a *phase*. This means that Bloch states that differ by a phase describe the same quantum state. In other words, each quantum state $|u_m(\mathbf{k})\rangle$ is a member of a *ray* (or *fiber*) of states each labeled by a phase

$$|(u_m)(\mathbf{k})\rangle \mapsto \exp(if_m(\mathbf{k})) |u_m(\mathbf{k})\rangle. \quad (282)$$

Changing the states by phase factors defines a $U(1)^M$ unitary transformation of physically equivalent states. Since we have a fiber at each point $\mathbf{k}$, this amounts at defining a *fiber bundle*. However, under this transformation, the Berry connection $\mathcal{A}_j^{(m)}(\mathbf{k})$ changes by a gradient of the phases

$$\mathcal{A}_j^{(m)}(\mathbf{k}) \mapsto \mathcal{A}_j^{(m)}(\mathbf{k}) + \partial_j f_m(\mathbf{k}) \quad (283)$$

where we assumed that the phases $f_m(\mathbf{k})$ are continuous and differentiable functions on the entire first Brillouin zone. Since the physical states cannot change by redefinitions of the phases of the basis states, we are led to the condition that only the data that is invariant under the gauge transformations defined by Eqs. (282) and (283) is physically meaningful, which is encoded in the gauge-invariant pseudo-scalar quantity $\mathcal{F}^{(m)}(\mathbf{k})$

$$\mathcal{F}^{(m)}(\mathbf{k}) = \epsilon_{ij} \partial_i \mathcal{A}_j^{(m)}(\mathbf{k}) \quad (284)$$

which is known as the *Berry curvature*.

In what follows we will be interested in the quantity

$$C_1^{(m)} = \frac{1}{2\pi} \oint_{\Gamma} dk_j \mathcal{A}_j^{(m)}(\mathbf{k}) = \frac{1}{2\pi} \int_{\text{BZ}} d^2 k \mathcal{F}^{(m)}(\mathbf{k}) \quad (285)$$

where Γ is the boundary of the 1st Brillouin zone (which we denote by BZ). We will now show that the quantity $C_1^{(m)}$, which measures the *flux* of the Berry connection $\mathcal{A}_j^{(m)}(\mathbf{k})$ through the first Brillouin zone (in units of 2π), is an integer independent of the particular connection $\mathcal{A}_j^{(m)}(\mathbf{k})$ that we have chosen. This integer-valued quantity is a topological invariant known as the first Chern number.

However, since the first Brillouin zone is a 2-torus, which is a closed manifold, a Berry connection with a net flux cannot obey periodic boundary conditions. Instead, we must allow for generalized (large) gauge transformations that wrap around the 2-torus of the first Brillouin zone. This problem is similar (and closely related) to the problem of the wave functions of a charged particle moving in the presence of a magnetic monopole (Wu and Yang, 1976). We will consider a 2D system whose first Brillouin zone is spanned by two reciprocal lattice vectors $\mathbf{b}_1$ and $\mathbf{b}_2$, related by the two primitive lattice vectors $\mathbf{a}_1$ and $\mathbf{a}_2$ by the relation $\mathbf{b}_i \cdot \mathbf{a}_j = 2\pi \delta_{ij}$ (with $i, j = 1, 2$). The generalized gauge transformations now are

$$\begin{aligned} |u_m(\mathbf{k} + \mathbf{b}_1)\rangle &= \exp(if_m^{(1)}(\mathbf{k})) |u_m(\mathbf{k})\rangle, & |u_m(\mathbf{k} + \mathbf{b}_2)\rangle &= \exp(if_m^{(2)}(\mathbf{k})) |u_m(\mathbf{k})\rangle \\ \mathcal{A}_j^{(m)}(\mathbf{k} + \mathbf{b}_1) &= \mathcal{A}_j^{(m)}(\mathbf{k}) + \partial_j f_m^{(1)}(\mathbf{k}), & \mathcal{A}_j^{(m)}(\mathbf{k} + \mathbf{b}_2) &= \mathcal{A}_j^{(m)}(\mathbf{k}) + \partial_j f_m^{(2)}(\mathbf{k}) \end{aligned} \quad (286)$$

where $f_m^{(1)}(\mathbf{k})$ and $f_m^{(2)}(\mathbf{k})$ are smooth functions of $\mathbf{k}$.

We will now show that the Bloch states cannot be defined globally over the Brillouin zone if the flux of the Berry connection does not vanish. More specifically let us assume that at some point $\mathbf{k}_0 \in T$, we know the Bloch state $|u_m(\mathbf{k}_0)\rangle$ which satisfies the generalized periodic boundary conditions of Eq. (286). The question is, can we determine the Bloch state at some other also *arbitrary* point $\mathbf{k}_0'$? We will know that there is a topological obstruction that does not allow it if the flux of the Berry phase is not zero. The reason is that the *phase* of the Bloch state cannot be defined since, in general, the Bloch state will vanish at some point of the Brillouin zone where the phase is undefined.

We will prove that this is true by following an elegant construction due to Mahito Kohmoto which goes as follows (Kohmoto, 1985): The Brillouin zone is a torus that, we will denote by T , can be regarded as the tensor product of two circles, $T \equiv S_1 \times S_1$. Let us split the torus T into two disjoint subsets (or patches) H_I and H_{II} such that $T = H_I \cup H_{II}$. We will assume that in region H_I , the Bloch state vanishes at some point $\mathbf{k}_0 \in T_I$ and that the Bloch state does not vanish for all points $\mathbf{k} \in H_{II}$. This means that we can choose the Bloch state $|u_m(\mathbf{k})\rangle$ to be real for all $\mathbf{k} \in H_{II}$. On the other hand, we can always assign some arbitrary phase to the Bloch state at $\mathbf{k}_0 \in T_I$. Once we have done that, we can extend the definition of the phase to a neighborhood of $\mathbf{k}_0$ wholly included in H_I . If we assume that there is only one zero, then the phase can be defined over all of H_I . The result is that we now have two different definitions of the phase of the Bloch state on H_I and on H_{II} . Let $|u_m(\mathbf{k})\rangle_I$ and $|u_m(\mathbf{k})\rangle_{II}$ be the two resulting definitions of the Bloch state. Let the closed curve γ be the common boundary of regions H_I and H_{II} , $\gamma = \partial H_I = \partial H_{II}$. However on the common boundary γ , these two definitions of the Bloch state must be a gauge transformation,

$$|u_m(\mathbf{k})\rangle_I = \exp(if_m(\mathbf{k})) |u_m(\mathbf{k})\rangle_{II} \quad (287)$$

on all points $\mathbf{k} \in \gamma$. The gauge transformation $f_m(\mathbf{k})$, known as the transition function, is a smooth periodic function of the points $\mathbf{k}$ on the closed curve γ . Likewise, the Berry connection $\mathcal{A}_j^{(m)}(\mathbf{k})$ has two definitions on the regions H_I and H_{II} , which differ by a gauge transformation on all the points $\mathbf{k}$ of the common boundary γ ,

$$\mathcal{A}_j^{(m)}(\mathbf{k})|_I - \mathcal{A}_j^{(m)}(\mathbf{k})|_{II} = \partial_j f_m(\mathbf{k}). \quad (288)$$

The transition function defines a mapping of the closed curve γ , which is topologically equivalent to a circle S_1 , to the phase of the Bloch state, which is defined mod 2π and hence is also a circle S_1 . Hence the transition functions $f_m(\mathbf{k})$ are homotopies that can be

classified by the homotopy group $\Pi_1(S_1) \simeq \mathbb{Z}$. We recognize that the classification of the transition functions is the same that we used for the vortices of Section “Vortices in two dimensions.” Hence, the change of the transition function on a full revolution of the closed curve γ must be an integer multiple of 2π .

We will now compute the quantity $C_1^{(m)}$, given in Eq. (285), which measures the flux of the Berry connection through the 2-torus T that defines the first Brillouin zone. Using the partition of the torus $T = T_I \cup T_{II}$, we can write

$$C_1^{(m)} = \frac{1}{2\pi} \int_T d^2k \mathcal{F}^{(m)}(\mathbf{k}) = \frac{1}{2\pi} \left(\int_{H_I} d^2k \mathcal{F}^{(m)}(\mathbf{k}) + \int_{H_{II}} d^2k \mathcal{F}^{(m)}(\mathbf{k}) \right) \quad (289)$$

Using Stokes Theorem on the two regions H_I and H_{II} , we get

$$C_1^{(m)} = \frac{1}{2\pi} \oint_\gamma dk_j \left(\mathcal{A}_j(\mathbf{k})|_I - \mathcal{A}_j(\mathbf{k})|_{II} \right). \quad (290)$$

Since the two definitions of the Berry connection differ by a gauge transformation, Eq. (288), we can express $C_1^{(m)}$ in terms of the transition function $f_m(\mathbf{k})$ on the curve γ

$$C_1^{(m)} = \frac{1}{2\pi} \oint_\gamma d\mathbf{k} \cdot \partial f_m(\mathbf{k}) = \frac{1}{2\pi} (\Delta f_m(\mathbf{k}))_\gamma = n \quad (291)$$

where we used that the transition functions are classified by the integer-valued quantity $n \in \mathbb{Z}$.

We conclude that the flux of the Berry curvature $C_1^{(m)}$ takes only integer values. It is known of the first Chern number $C_1^{(m)}$, which is a topological invariant since it cannot change by a smooth redefinition of the curve γ . Since $C_1^{(m)} \neq 0$ implies that the Bloch states must vanish at least at some point (or points) $\mathbf{k} \in H_I$, then the integer-valued Chern number can only change if a redefinition of the curve γ crosses at least one point $\mathbf{k}$ at which the Bloch state vanishes.

The conclusion of this analysis is that whenever the flux of the Berry curvature through the Brillouin zone does not vanish, the Bloch states cannot be defined globally on the Brillouin zone. A direct consequence is that in this case the band is characterized by a topological invariant called the first Chern number. This number is a property of a given band and, in general, it is different for each band. This is a particular case of a more general topological classification of the states of free fermions on a lattice which depends on the dimensionality of the system (Schnyder et al., 2008; Kitaev, 2009; Moore and Balents, 2007).

The quantum Hall effect on a lattice

We will now show that 2D free fermion systems with Chern bands, that is, bands characterized by a nonvanishing Chern number, are insulators that have a quantized Hall conductivity. We will do this for the theory of the integer quantum Hall effect on a 2D lattice of Thouless, Kohmoto, Nightingale and den Nijs (TKNN) (Thouless et al., 1982; Kohmoto, 1985) [see also, Fradkin and Kohmoto (1987)]. Although this problem played a key role in the development of the theory of topological phases of matter, for many years it was viewed as an academic problem since it would require gigantic magnetic fields to be in the regime of interest for typical solids. The situation changed with the development of twisted bilayer graphene and similar systems which have unit cells large enough for this physics to be observable. These new materials have allowed to study this problem experimentally.

TKNN considered a system of free fermions on a planar (actually square) lattice in a uniform magnetic field B with flux $2\pi p/q$ per plaquette (in units in which the flux quantum $\phi_0 = e\hbar/c = 1$) with p and q two co-prime integers. The tight-binding Hamiltonian for this simple problem is

$$H = \sum_{\mathbf{r}, j=1,2} t_j c^\dagger(\mathbf{r}) e^{iA_j(\mathbf{r})} c(\mathbf{r} + \mathbf{e}_j) + \text{h.c.} \quad (292)$$

where $c(\mathbf{r})$ and $c^\dagger(\mathbf{r})$ are fermion creation and annihilation operators on the lattices sites $\{\mathbf{r} = (m, n)\}$, $\mathbf{e}_j$ are lattice unit vectors, and t_j , with $j = x, y$, is a hopping matrix element between nearest neighbor sites of the square lattice along the x and y directions. On each link of the lattice, we defined a vector potential $A_j(\mathbf{r})$, where the oriented sum of the lattice vector potentials on each plaquette $2\pi\phi$, where $\phi = \frac{p}{q}$, is the flux on each plaquette of the square lattice. In the axial (Landau) gauge $A_1(m, n) = 0$, $A_2(m, n) = 2\pi m\phi$ is a periodic function of m with period q . In this gauge, the Hamiltonian becomes

$$H = t \sum_{m,n} (c^\dagger(m+1, n) c(m, n) + c^\dagger(m, n) c(m+1, n)) \\ + t \sum_{m,n} (c^\dagger(m, n+1) e^{i2\pi\phi m} c(m, n) + c^\dagger(m, n) e^{-i2\pi\phi m} c(m, n+1)) \quad (293)$$

In this gauge, the problem reduces to a system with a theory with a $q \times 1$ unit cell with q inequivalent sites. In momentum space, the (magnetic) Brillouin zone of this system is $-\frac{\pi}{q} \leq k_1 \leq \frac{\pi}{q}$ and $-\pi \leq k_2 \leq \pi$. The Fourier transform of the operators $c^\dagger(\mathbf{r})$ and $c(\mathbf{r})$ is, respectively, $c^\dagger(\mathbf{k})$ and $c(\mathbf{k})$, which obey the standard anticommutation relations, $\{c(\mathbf{k}), c(\mathbf{q})\} = \{c^\dagger(\mathbf{k}), c^\dagger(\mathbf{q})\} = 0$, and $\{c^\dagger(\mathbf{k}), c(\mathbf{q})\} = \delta(\mathbf{k} - \mathbf{q})$. In momentum space, the Hamiltonian becomes

$$H = q \int_{-\pi/q}^{\pi/q} \frac{dk_x}{2\pi} \int_{-\pi}^{\pi} \frac{dk_y}{2\pi} \tilde{H}(k_x, k_y) \quad (294)$$

where

$$\begin{aligned} \tilde{H}(k_x, k_y) = \frac{1}{q} \sum_{n=0}^{q-1} \{ & 2t_x \cos(k_x + 2\pi\phi n) c^\dagger(k_x + 2\pi\phi n, k_y) c(k_x + 2\pi\phi n, k_y) \\ & + t_y [e^{-ik_y} c^\dagger(k_x + 2\pi(n+1)\phi, k_y) c(k_x + 2\pi n\phi, k_y) + e^{ik_y} c^\dagger(k_x + 2\pi(n-1)\phi, k_y) c(k_x + 2\pi n\phi, k_y)] \} \end{aligned} \quad (295)$$

The spectrum of this system was first investigated by Hofstadter (1876) consists of q bands which for q an odd integer are separated by finite energy gaps.

For fixed values of k_x and k_y (in the magnetic Brillouin zone), the Hamiltonian $\tilde{H}(k_x, k_y)$ is the tight-binding model of a one-dimensional chain on the 1D lattice of q sites located at $k_x + 2\pi n\phi$ with nearest neighbor hopping. The single-particle (Bloch) states $u_n(\mathbf{k})$ of this 1D model obeys the Schrödinger Equation

$$2t_x \cos(k_x + 2\pi n\phi) u_n(\mathbf{k}) + t_y (e^{-ik_y} u_{n-1}(\mathbf{k}) + e^{ik_y} u_{n+1}(\mathbf{k})) = E_n u_n \quad (296)$$

which is known as Harper's equation. In general, this equation does not admit an analytic solution. However, the nature qualitative features of the spectrum can be obtained by an expansion either on t_x/t_y or on t_y/t_x . TKNN used degenerate perturbation theory to show that the spectrum has q bands and that the r -th band is characterized by two integers s_r and ℓ_r , which are the solution of the Diophantine equation

$$r = q s_r + p \ell_r \quad (297)$$

with $\ell_0 = s_0 = 0$. It is also obvious that for $r = q s_q = 1$ and $\ell_q = 0$ (for all p).

Furthermore, TKNN showed that there was an, until then unsuspected, relation between the Hall conductivity σ_{xy} of a gapped system of electrons in periodic potentials in a uniform magnetic field and the Berry connection of the filled bands. This relation implies the quantization of the Hall conductivity and its computation in terms of a topological invariant, the Chern number of the occupied bands. They showed that in this context, each band has a nontrivial Berry connection $\mathcal{A}_j^{(r)} = i \langle u_r(\mathbf{k}) | \partial_j | u_r(\mathbf{k}) \rangle$ (with $\partial_j = \partial_{k_j}$) of the form of Eq. (281) with a nonvanishing (first) Chern number $C_1^{(r)}$, that is, the flux through the magnetic Brillouin zone.

The conductivity tensor characterizes the electrical properties of a physical system. Linear Response Theory provides a framework for computing the conductivity tensor by perturbing the system with a weak external electromagnetic field A_μ and computing the currents that they induce (Martin, 1967; Fradkin, 2021). The expectation value of the gauge-invariant current operator $J_\mu(x)$ is

$$\langle J_\mu(x) \rangle = -\frac{i}{\hbar} \frac{\delta}{\delta A_\mu(x)} \ln Z[A_\mu] \quad (298)$$

where $Z[A_\mu]$ is the partition function in the presence of a background (i.e., classical) electromagnetic field $A_\mu(x)$. In general spacetime dimension $D = d + 1$, the lowest order in the vector potential A_μ the induced current is given in terms of the polarization tensor $\Pi_{\mu\nu}(x, y)$

$$\ln Z[A_\mu] = \frac{i}{2} \int d^D x \int d^D y A_\mu(x) \Pi^{\mu\nu}(x, y) A_\nu(y) + O(A^3). \quad (299)$$

Therefore, the induced current is related to the external field by

$$\langle J_\mu(x) \rangle \equiv J_\mu(x) = \int d^D y \Pi_{\mu\nu}(x, y) A^\nu(y). \quad (300)$$

Expressions of this type are known as a *Kubo formula*. The polarization tensor can be regarded as a *generalized susceptibility*.

Although we are using a continuum relativistic notation, these expressions are generally valid, even in lattice systems. Gauge invariance requires that the polarization tensor be conserved

$$\partial_\mu \Pi^{\mu\nu}(x, y) = 0. \quad (301)$$

In general, the (retarded) polarization tensor $\Pi^{\mu\nu}(x, y)$ is related to the (retarded) current-current correlation function $\mathcal{D}_{\mu\nu}^R(x, y)$,

$$\mathcal{D}^{\mu\nu}(x, y) = -\frac{i}{\hbar} \Theta(x_0 - y_0) \langle [J_\mu(x), J_\nu(y)] \rangle \quad (302)$$

by the identity

$$\Pi_{\mu\nu}^R(x, y) = \mathcal{D}_{\mu\nu}^R(x, y) - i\hbar \left\langle \frac{\delta J_\mu(x)}{\delta A_\nu(y)} \right\rangle. \quad (303)$$

The last term in Eq. (303) is usually called a “contact term.” This term vanishes only for a theory of relativistic fermions (in the continuum). In all other cases, lattice or continuum, relativistic or not, the contact term does not vanish and its form depends on the specific theory. In nonrelativistic systems, for example, in a FL, this term is the origin of the f -sum rule (Martin, 1967; Nozières and Pines, 1966).

When the external field A_μ represents is a (locally) uniform electric field E , the induced current is $J_i = \sigma_{ij}E_j$, where σ_{ij} is the conductivity tensor, which can be obtained from the polarization tensor as the limit

$$\sigma_{ij} = \lim_{\omega \rightarrow 0} \frac{1}{i\omega} \lim_{q \rightarrow 0} \Pi_{ij}(\omega, q) \quad (304)$$

In a metal, which has a Fermi surface, the order of limits in which ω and q vanish matters and only the order of limits specified above is the correct one to take. In Dirac systems, that we will discuss below, the order does not matter due to relativistic invariance. The other case in which the order does not matter is the Chern insulator that we are interested in. In general, in an isotropic system, the conductivity tensor has a symmetric part and an antisymmetric part. The symmetric part of the conductivity tensor yields the longitudinal conductivity, which has all the effects of dissipation. The antisymmetric part does not vanish in the presence of a magnetic field or, more generally, if time reversal symmetry is broken, and yields the Hall conductivity.

A Chern insulator is an insulator and as such is a state with an energy gap. In such a state, the longitudinal conductivity vanishes since there is no dissipation in a gapped state. But in a Chern insulator time-reversal invariance is broken. In the system that we are discussing is broken by the magnetic field. The Hall conductivity can be calculated from the antisymmetric part of the polarization tensor as the limit

$$\sigma_{xy} = \lim_{\omega \rightarrow 0} \frac{i}{\omega} \Pi_{xy}(\omega, 0). \quad (305)$$

In addition, the contact term does not contribute to the Hall conductivity. As a result, the hall conductivity can be computed in terms of the antisymmetric component of the current-correlation function.

Let us now return to the theory of free fermions on a lattice in a (commensurate) magnetic field takes. As we saw, the electronic states are split into q bands with single particle states $|\psi_n(\mathbf{k})\rangle$ where $\mathbf{k}$ takes values on the first magnetic Brillouin zone. We will compute the Hall conductivity for this system assuming that the Fermi energy E_F lies in the gap between the n -th and the $n-1$ -th bands. Let us label by α the occupied bands and by β the unoccupied bands. Hence $E_\alpha(\mathbf{k}) < E_F < E_\beta(\mathbf{k})$. In this case, the Kubo formula for the Hall conductivity becomes

$$\sigma_{xy} = i \frac{e^2}{\hbar} \sum_{E_\alpha < E_F < E_\beta} \int_{BZ} \frac{d^2k}{(2\pi)^2} \frac{\langle u_\alpha(\mathbf{k}) | J_y | u_\beta(\mathbf{k}) \rangle \langle u_\beta(\mathbf{k}) | J_x | u_\alpha(\mathbf{k}) \rangle - \langle u_\alpha(\mathbf{k}) | J_x | u_\beta(\mathbf{k}) \rangle \langle u_\beta(\mathbf{k}) | J_y | u_\alpha(\mathbf{k}) \rangle}{(E_\alpha(\mathbf{k}) - E_\beta(\mathbf{k}))^2}. \quad (306)$$

In the lattice model, the current operator is simply

$$\mathbf{J} = \frac{e}{\hbar} \partial_{\mathbf{k}} \tilde{H}(\mathbf{k}) \quad (307)$$

Using this form of the current and the Schrödinger equation of Eq. (296), we can rewrite the Kubo formula for the Hall conductivity, Eq. (306), as a sum over only the occupied states labeled by α . The expression for the Hall conductivity now takes the more compact form

$$\sigma_{xy} = \frac{e^2}{\hbar} \sum_{\alpha} \int_{BZ} \frac{d^2k}{(2\pi)^2} \epsilon_{ji} \partial_j \langle u_\alpha(\mathbf{k}) | \partial_k | u_\alpha(\mathbf{k}) \rangle = \frac{e^2}{\hbar} \sum_{\alpha} \frac{1}{2\pi} \int_{BZ} \mathcal{F}^{(x)}(\mathbf{k}) = \frac{e^2}{\hbar} \sum_{\alpha} C_1^{(x)}. \quad (308)$$

Therefore, we conclude that each occupied band contributes to the Hall conductivity an amount equal to its first Chern number (multiplied by $e^2/\hbar$). This is the main result of TKNN (Thouless et al., 1982).

In the specific case of the model that we are discussing here, the Chern number is given explicitly in terms of the solution of the Diophantine equation, Eq. (297)

$$C_1^{(r)} = \frac{1}{2\pi} \oint_{\Gamma} dk_j \mathcal{A}_j^{(r)}(\mathbf{k}) = \ell_r - \ell_{r-1} \quad (309)$$

where the integers ℓ_r and ℓ_{r-1} are the solutions of the Diophantine equation for the bands r and $r-1$ (A detailed derivation can be found in Fradkin (2013), Chapter 12). The TKNN integers ℓ_r are topological invariants of the bands.

We conclude, with TKNN, that for a system with r filled bands, the Hall conductivity $\sigma_{xy}^{(r)}$ is given by the expression

$$\sigma_{xy}^{(r)} = \frac{e^2}{\hbar} \sum_{n=1}^r (\ell_r - \ell_{n-1}) = \frac{e^2}{\hbar} \ell_r \quad (310)$$

thus showing that this system exhibits an integer quantum Hall effect and that the Hall conductivity is (up to the ratio of universal constants $e^2/\hbar$) given by a topological invariant, the first Chern number of the band.

We conclude with two comments. The first is that when *all* the bands are occupied, the Hall conductivity vanishes. This obvious physical constraint is automatically satisfied by the Diophantine equation. The other comment concerns the case of what happens when q is an even integer. In this case it is possible to show that there are band crossings. This is what happens for $q=2$, which is the π flux lattice. In this case, one has a theory of two species of Dirac bi-spinors. As we will see in Section “The anomalous quantum Hall effect,” what happens depends on how the gapless state is reached.

The anomalous quantum Hall effect

We will now discuss a simple and insightful model of a Chern insulator that displays the quantum anomalous Hall effect, that is, a Hall effect in a system with broken time reversal symmetry in the absence of a uniform magnetic field. In order to do that, we will reconsider the graphene model with additional terms in the Hamiltonian of Eq. (280) that will open up energy gaps in its spectrum. There are several ways to do this. One way requires breaking the symmetry between the two sublattices A and B , by assigning them a site energy of $\pm M$, which breaks the mirror reflection symmetry of the hexagon. This is what happens with graphene on a boron nitride substrate (Semenoff, 1984) [there are other ways that involve breaking the point group symmetry (Ryu et al., 2009)]. Another way to open a gap is to break time reversal symmetry, which is accomplished by complex hopping amplitudes $t_2 \exp(i\phi)$ between nearest neighbor A sites (and between nearest neighbor B sites as well). The phase ϕ is oriented from r_A to $r_A + \mathbf{a}_i$, where $\mathbf{a}_1 = \mathbf{d}_2 - \mathbf{d}_3$, etc. (and similarly for the B sites). Physically, the oriented sum of the phases ϕ on the triangles generated by the hopping terms t_1 and t_2 represents the magnetic fluxes through each triangle such that the total flux on the elementary hexagon is zero. This model was considered by Haldane (1988a). With these changes, the one-particle Hamiltonian becomes 2×2 Hermitian matrix

$$H(\mathbf{k}) = h_0(\mathbf{k}) \mathbf{1} + \mathbf{h}(\mathbf{k}) \cdot \boldsymbol{\sigma} \quad (311)$$

where $\mathbf{1}$ is the 2×2 identity matrix and $\boldsymbol{\sigma} = (\sigma_1, \sigma_2, \sigma_3)$ is a vector made of the three Pauli matrices. The functions $h_0(\mathbf{k})$ and $\mathbf{h}(\mathbf{k}) = (h_1(\mathbf{k}), h_2(\mathbf{k}), h_3(\mathbf{k}))$ are, respectively, given by

$$\begin{aligned} h_0(\mathbf{k}) &= 2t_2 \cos \phi \sum_{i=1,2,3} \cos(\mathbf{k} \cdot \mathbf{a}_i), & h_1(\mathbf{k}) &= t_1 \sum_{i=1,2,3} \cos(\mathbf{k} \cdot \mathbf{d}_i), \\ h_2(\mathbf{k}) &= t_1 \sum_{i=1,2,3} \sin(\mathbf{k} \cdot \mathbf{d}_i), & h_3(\mathbf{k}) &= M - 2t_2 \sin \phi \sum_{i=1,2,3} \sin(\mathbf{k} \cdot \mathbf{a}_i). \end{aligned} \quad (312)$$

Provided $|t_2/t_1| < 1/3$, the spectrum of the Hamiltonian of Eq. (280) has two bands that do not overlap and have a finite energy gap unless they cross at the corners K and K' , the Brillouin zone where the gap is smallest. The two bands cross at K and/or K' if $M = \pm 3\sqrt{3}t_2 \sin \phi$ (for K and K' , respectively). When either one of these conditions is not met, the spectrum is gapped at either K or K' or, more generally, at both. For values of the parameters for which the band gaps are small, the low energy states of the Hamiltonian of Eq. (280) is that of a theory of two Dirac fields, that we will label as $\psi_1(x)$ and $\psi_2(x)$, whose one-particle Hamiltonians have the form of Eq. (275) but with generally different masses $m_1 \propto M - 3\sqrt{3}t_2 \sin \phi$ and $m_2 \propto M + 3\sqrt{3}t_2 \sin \phi$. So, in general, both fields will have nonvanishing masses, which can have the same sign or opposite sign.

We conclude that the effective low-energy theory consists of two species of massive Dirac bi-spinors, albeit generally with different masses. To examine the electromagnetic response, we will couple the lattice model and the effective low energy theory to a slowly varying background electromagnetic field A_μ . The Lagrangian of the low energy theory is

$$\mathcal{L} = \bar{\psi}_1 (i\partial - m_1) \psi_1 + \bar{\psi}_2 (i\partial - m_2) \psi_2 - eA_\mu (\bar{\psi}_1 \gamma^\mu \psi_1 + \bar{\psi}_2 \gamma^\mu \psi_2). \quad (313)$$

In general, the two masses will be different in magnitude and sign. Equivalently the Dirac fermions may have the same or opposite chirality. We will examine the electromagnetic response for both cases in Section “The parity anomaly” where we will see that in the phase in which the masses of both Dirac fermions have the same sign, this model describes a topological insulator that exhibits the anomalous quantum Hall effect, whereas in the phase where the signs are opposite, it is a conventional insulator.

However, by varying the parameters, we can tune to special values of these parameters where one of the two masses vanishes. In Section “The parity anomaly,” we will see that these special values of the parameters correspond to quantum phase transitions at which the topological properties of the ground state change. We will see that this is a quantum critical point with special properties. In particular, time-reversal invariance is explicitly broken at this quantum critical point. In this regime, the heavy Dirac fermion plays the role of the heavy regulating field as in the Pauli–Villars regularization of the theory of a single Dirac fermion. In the lattice model, this is a manifestation of the Nielsen–Ninomiya theorem which requires that there should be an even number of Dirac fermions (Nielsen and Ninomiya, 1981a, b; Friedan, 1982). In this context, the heavy fermion is the “doubler.”

The parity anomaly

We saw in Section “The chiral anomaly” that Dirac fermions in 1+1 dimensions have a chiral anomaly. That statement mean, that although the theory of free massless Dirac fermions has a global chiral symmetry, the associated current, which we called j_μ^5 , is not conserved when the system is coupled to an external gauge field. This effect happened because the right and left moving (Weyl) components of the massless Dirac fermion cannot be separately conserved in the presence of a gauge field.

Analogues of the 1+1-dimensional chiral anomaly exist on 3+1 dimensions (and, more generally, in all even spacetime dimensions). The cancelation of these anomalies is a key condition for the consistency of gauge theories (’t Hooft, 1976b). We will see in Section “Topological phases of matter” that these anomalies play a role on the theory of 3D topological insulators. More generally, anomalies play a central role in the theory of symmetry-protected topological (SPT) phases of matter (Chen et al., 2012; Senthil, 2015; Witten, 2016).

Dirac fermions in 2+1 dimensions do not have an analog of the chiral anomaly for the simple reason that the chiral symmetry does not exist. There is, however, an anomaly involving parity or, equivalently, time-reversal invariance, known as the parity anomaly. The parity anomaly was discovered in the computation of the effective action of the electromagnetic field in a theory of massive Dirac fermions in 2+1 dimensions by Redlich (1984a,b).

Consider theory on a single massive Dirac fermion (a bi-spinor) $\psi(x)$ in 2+1 dimensions coupled to a background $U(1)$ gauge field A_μ . The Lagrangian is

$$\mathcal{L}[\psi, \bar{\psi}, A_\mu] = \bar{\psi} i \mathbb{D} \psi - m \bar{\psi} \psi \quad (314)$$

where the covariant derivative is $D_\mu = \partial_\mu + i A_\mu$. The effective action $S_{\text{eff}}[A_\mu]$ of the gauge field A_μ is formally obtained by computing the path integral

$$Z[A_\mu] = \exp(i S_{\text{eff}}[A_\mu]) = \int \mathcal{D}\psi \mathcal{D}\bar{\psi} \exp(i \int d^3x \mathcal{L}[\psi, \bar{\psi}, A_\mu]) = \text{Det}(i \mathbb{D}[A_\mu] - m) \quad (315)$$

where we used that the theory is free to write the partition function as a functional determinant. In 1+1 dimensions, in the case of a massless theory, this determinant can be computed exactly using the heat kernel (or zeta-function) technique (Fujikawa, 1979; Gamboa Saraví et al., 1984). Aside from important technicalities, the reason for why this works is that as a consequence of the chiral anomaly, the effective action computed at one loop order in the fermions is exact in 1+1 dimensions. In higher dimensions, this is no longer true.

We will sketch the computation of the effective action to one loop order, which means quadratic in the gauge field A_μ , which has the form

$$S_{\text{eff}}[A_\mu] = \frac{1}{2} \int d^3x \int d^3y A_\mu(x) \Pi^{\mu\nu}(x-y) A_\nu(y) + \dots \quad (316)$$

where the ellipsis contains the higher order contributions. The polarization operator $\Pi^{\mu\nu}(x-y)$ in momentum space is (here p_μ is the momentum transfer) by the one-loop result

$$\Pi^{\mu\nu}(p) = \int \frac{d^3q}{(2\pi)^3} \text{tr}[S(q+p/2) \gamma^\mu S(q-p/2) \gamma^\nu]. \quad (317)$$

The symbol tr signifies the trace over the spinor labels and $S(p)$ is the (massive) Feynman propagator

$$S(p) = \frac{1}{\not{p} - m + i\epsilon}. \quad (318)$$

The polarization tensor $\Pi^{\mu\nu}(p)$ has the explicit decomposition into a parity even and a parity odd contributions

$$\Pi^{\mu\nu}(p) = (p^2 g^{\mu\nu} - p^\mu p^\nu) \Pi_0(p^2) - i \epsilon^{\mu\nu\lambda} p_\lambda \Pi_A(p^2) \quad (319)$$

where $p^2 = p_0^2 - \mathbf{p}^2$. The polarization tensor is manifestly transverse, $p_\mu \Pi^{\mu\nu}(p) = 0$ and, hence, the one-loop effective action of Eq. (316) is gauge-invariant (as it should be). The parity even $\Pi_0(p^2)$ and parity odd $\Pi_A(p^2)$ kernels are given by

$$\Pi_0(p^2) = -\frac{|m|}{4\pi p^2} + \frac{1}{8\pi\sqrt{p^2}} \left(\frac{4m^2}{p^2} + 1 \right) \sinh^{-1} \left(\frac{\sqrt{p^2}}{\sqrt{4m^2 - p^2}} \right) \quad (320)$$

$$\Pi_A(p^2) = -\frac{m}{2\pi\sqrt{p^2}} \sinh^{-1} \left(\frac{\sqrt{p^2}}{\sqrt{4m^2 - p^2}} \right). \quad (321)$$

These two results are obtained in the limit in which the regulator scales are sent to infinity leaving behind these finite results, which hold provided the Dirac mass m does not vanish.

In the low-energy regime, $|p^2| \ll m^2$, the kernels take the asymptotic values

$$\Pi_0(p^2) \simeq \frac{1}{16\pi|m|} \quad \Pi_A(p^2) \simeq -\frac{1}{4\pi} \text{sgn}(m). \quad (322)$$

This result is the leading contribution to the parity even term (the first term) up to corrections of the order of p^2/m^2 . However, the second term, which is parity odd, is the exact contribution in the limit $p \rightarrow 0$ for all nonvanishing values of the Dirac mass. In this regime, the effective Lagrangian of the gauge field A_μ takes the local form of the sum of a Maxwell term and a Chern–Simons term

$$\mathcal{L}_{\text{eff}}[A_\mu] = -\frac{1}{4\pi|m|} F_{\mu\nu} F^{\mu\nu} \pm \frac{1}{2} \frac{1}{4\pi} \epsilon_{\mu\nu\lambda} A^\mu \partial^\nu A^\lambda \quad (323)$$

where $F_{\mu\nu} = \partial_\nu A_\mu - \partial_\mu A_\nu$ is the field strength of the gauge field. Clearly, since the Maxwell term has two derivatives while the Chern–Simons term has one derivative, in the long-distance regime the Maxwell term is irrelevant (subdominant). Also, while the prefactor of the Chern–Simons term is a pure number, the prefactor of the Maxwell term is proportional to $\frac{1}{|m|}$ (as required by dimensional analysis).

The second term in the Lagrangian of Eq. (323) is a Chern–Simons term for the background gauge field A_μ (Deser et al., 1982a,b). This term is gauge-invariant (up to boundary terms) but breaks parity and time-reversal invariance. This phenomenon is called the *parity anomaly* (Redlich, 1984a), although Witten (2016) has argued that it is better to call this phenomenon a *time-reversal anomaly*.

The *sign* of the prefactor of the Chern–Simons term depends on the *sign* of the Dirac mass m : positive for $m > 0$ and negative for $m < 0$ or, alternatively for positive and negative chirality of the Dirac (bi-spinor) field which fixes the sign of the breaking of time-reversal invariance.

In addition to the sign, the prefactor of the Chern–Simons term is equal to $\frac{1}{2}$, and it is not an integer. In Section “Vacuum degeneracy a torus,” we showed that for a *dynamical* Chern–Simons gauge theory to be defined consistently on a closed surface, this coefficient must be quantized and should take *integer* values. The fact that the coefficient is half-quantized means that the classical global symmetry of a theory of a single Dirac bi-spinor cannot be gauged, which means that the gauge theory cannot be quantized. This is an example of an obstruction to the quantization of a gauge theory due to an anomaly (‘t Hooft, 1976b).

We will now use these results to compute the effective low-energy action for the theories of lattice Dirac fermions of Section “Dirac fermions and topological insulators.” In those systems, the low energy theory is that of *two* Dirac (bi-spinors) with different masses m_1 and m_2 . Since both Dirac fields are coupled (minimally) to the same background gauge field A_μ , the effective Lagrangian is just the sum of the contribution for each Dirac fermion

$$\mathcal{L}_{\text{eff}}[A_\mu] = -\frac{1}{4\pi|m|_{\text{eff}}} F_{\mu\nu} F^{\mu\nu} + \frac{1}{2} (\text{sgn}(m_1) + \text{sgn}(m_2)) \frac{1}{4\pi} \epsilon_{\mu\nu\lambda} A^\mu \partial^\nu A^\lambda \quad (324)$$

where $|m|_{\text{eff}}$ is

$$\frac{1}{|m|_{\text{eff}}} = \frac{1}{|m_1|} + \frac{1}{|m_2|}. \quad (325)$$

This result implies that, as anticipated in Section “Dirac fermions and topological insulators,” this theory has two phases: a parity even phase and a parity-odd phase. In the regime in which the signs of the two mass terms are equal and opposite, $\text{sgn}(m_1) = -\text{sgn}(m_2)$, the coefficient of the Chern–Simons term cancels and the low-energy effective Lagrangian is a Maxwell term (generally with an effective speed of light much smaller than that in vacuum): this phase is a conventional insulator.

Conversely, in the phase in which the two masses have the same sign, $\text{sgn}(m_1) = \text{sgn}(m_2)$, the coefficient of the Chern–Simons terms does not cancel, and it is given by $\pm \frac{1}{4\pi}$ where the sign is the sign of both mass terms. This phase is also an insulator but one in which time-reversal invariance is broken. Moreover, in this phase, the induced current j_μ by the background field A_μ in the long-distance limit is controlled by the Chern–Simons term, and it is given by

$$j_\mu = \frac{\delta \mathcal{L}_{\text{eff}}}{\delta A_\mu(x)} = \pm \frac{e^2}{2\pi\hbar} \epsilon_{\mu\nu\lambda} \partial^\nu A^\lambda. \quad (326)$$

From this result, we see that in the parity-broken anomalous quantum Hall phase, the system has a correctly quantized and nonvanishing Hall conductivity

$$\sigma_{xy} = \pm \frac{e^2}{h}. \quad (327)$$

Therefore, the phase with $\text{sgn}(m_1) = \text{sgn}(m_2)$ displays the *quantum anomalous Hall* effect with a Hall conductivity whose sign equals the signs of both masses. Notice that this is true regardless the magnitudes of the masses m_1 and m_2 , and that only their signs matter. In Section “Topological insulators,” we will identify this phase with a topological phase of matter known as the *Chern Insulator*.

We showed that the Hall conductivity of the anomalous quantum Hall phase is, as expected, equal to e^2/h using the effective low energy Dirac theory. One may wonder if this approximation may be missing some contributions to the Hall conductivity. Fortunately there is an alternative, quite elegant way of computing the Hall conductivity as a property of the entire occupied band. This approach, originally introduced by Volovik (1987) in the context of superfluid $^3\text{He-A}$, and adapted to the theory of the quantum anomalous Hall effect by Yakovenko (1990), by Maarten Golterman, Karl Jansen, and David Kaplan for a theory of Wilson fermions in odd dimensional hypercubic lattices (Golterman et al., 1993), and by Qi et al. (2006), involves the derivation of a topological invariant for a two-band model.

As we saw above, the Hall conductivity is obtained from the xy component of the polarization operator as the limit

$$\sigma_{xy} = \lim_{\omega \rightarrow 0} \frac{i}{\omega} \lim_{q \rightarrow 0} \Pi_{xy}(\omega, q). \quad (328)$$

For a free fermion system, $\Pi_{xy}(\omega, 0)$ is given by the current correlator

$$\Pi_{xy}(\omega, 0) = \int_{\text{BZ}} \frac{d^2 k}{(2\pi)^2} \int_{-\infty}^{\infty} \frac{d\Omega}{2\pi} \text{tr} [J_x(\mathbf{k}) G(\mathbf{k}, \omega + \Omega) J_y(\mathbf{k}) G(\mathbf{k}, \Omega)] \quad (329)$$

where $G(\mathbf{k}, \Omega)$ is the propagator for a two-band free fermion system. A generic two-band free fermion system has a one-particle Hamiltonian of the form given in Eq. (311). The (one-body) current operator for such a system is obtained as

$$J_i(\mathbf{k}) = \frac{\partial h_0(\mathbf{k})}{\partial k_i} \mathbf{1} + \frac{\partial h_a(\mathbf{k})}{\partial k_i} \sigma_a. \quad (330)$$

The propagator $G(\mathbf{k}, \omega)$ is the 2×2 matrix (in band indices)

$$G(\mathbf{k}, \omega) = \frac{1}{\omega \mathbf{1} - \mathbf{h}(\mathbf{k}) \cdot \boldsymbol{\sigma} + i\epsilon} = \frac{P_+(\mathbf{k})}{\omega - E_+(\mathbf{k}) + i\epsilon} + \frac{P_-(\mathbf{k})}{\omega - E_-(\mathbf{k}) + i\epsilon} \quad (331)$$

where $P_{\pm}(\mathbf{k})$ are the operators that project onto the (empty) conduction band and the (filled) valence band whose energies are, respectively $E_{\pm}(\mathbf{k})$,

$$P_{\pm}(\mathbf{k}) = \frac{1}{2} \left(\mathbf{1} \pm \hat{\mathbf{h}}(\mathbf{k}) \cdot \boldsymbol{\sigma} \right) \quad (332)$$

where $\hat{\mathbf{h}}(\mathbf{k})$ is the unit vector defined for every momentum $\mathbf{k}$ of the first Brillouin zone

$$\hat{\mathbf{h}}(\mathbf{k}) = \frac{\mathbf{h}(\mathbf{k})}{\|\mathbf{h}(\mathbf{k})\|}. \quad (333)$$

Upon performing the frequency integration and the band traces in the expression for $\Pi_{xy}(\omega, 0)$ of Eq. (329), we find that the Hall conductivity takes the form

$$\sigma_{xy} = \frac{e^2}{2\hbar} \int_{\text{BZ}} \frac{d^2 k}{(2\pi)^2} \epsilon_{abc} \frac{\partial \hat{h}_a(\mathbf{k})}{\partial k_x} \frac{\partial \hat{h}_b(\mathbf{k})}{\partial k_y} \hat{h}_c(\mathbf{k}) (n_+(\mathbf{k}) - n_-(\mathbf{k})) \quad (334)$$

where $n_{\pm}(\mathbf{k})$ are the Fermi functions (at zero temperature) for the two bands. Since

$$E_+(\mathbf{k}) - E_-(\mathbf{k}) = 2\|\mathbf{h}(\mathbf{k})\| = 2\sqrt{\mathbf{h}^2(\mathbf{k})} > 0 \quad (335)$$

there is a nonvanishing gap on the entire Brillouin zone between the occupied valence band, with $n_-(\mathbf{k}) = 1$, and the unoccupied conduction band, with $n_+(\mathbf{k}) = 0$. For the insulating state, the Fermi energy lies inside this gap and the expression for the Hall conductivity reduces to the following

$$\sigma_{xy} = -\frac{e^2}{2\hbar} \int_{\text{BZ}} \frac{d^2 k}{(2\pi)^2} \epsilon_{abc} \frac{\partial \hat{h}_a(\mathbf{k})}{\partial k_x} \frac{\partial \hat{h}_b(\mathbf{k})}{\partial k_y} \hat{h}_c(\mathbf{k}). \quad (336)$$

In our discussion of quantum antiferromagnets in one space dimensions in Section “Nonlinear sigma models and antiferromagnetic quantum spin chains,” we found that their effective low-energy action contained a crucial topological term proportional to the integer-valued topological invariant Q (the winding number) of Eq. (103) which classifies the smooth maps (homotopies) of the 2D surface (say a sphere S^2) onto the target space of a three-component unit vector field which also a sphere S^2 . These equivalence classes are represented by the notation $\Pi_2(S^2) \simeq \mathbb{Z}$. In the case at hand, the unit vector $\hat{\mathbf{h}}(\mathbf{k})$ are points on a 2-sphere. Hence, $\hat{\mathbf{h}}(\mathbf{k})$ is a map of the first Brillouin zone (which is a 2-torus) to the sphere S^2 . Such maps are also classified by the same integer-valued topological invariant defined in Eq. (103). These results imply that the Hall conductivity of the two-band system is

$$\sigma_{xy} = \frac{e^2}{2\pi\hbar} Q[\hat{\mathbf{h}}]. \quad (337)$$

In other words, we have shown that the Hall conductivity is given in terms of a topological invariant of the occupied band (in units of e^2/h), the winding number Q . In the two-band model the topological invariant Q plays the same role as the Chern number does in the work of TKNN (Thouless et al., 1982; Kohmoto, 1985). When $Q \neq 0$, the two-band system exhibits the quantized anomalous quantum Hall effect. This is a property of the entire band of occupied states, and not just a consequence of the low energy approximation. This result implies that the low energy approximation captures all of the topology of the band. It also implies that in these lattice models, the Berry curvature is highly concentrated near the points in momentum space where the two bands are close in energy.

We will now consider the problem of the quantum phase transition between the trivial and the Chern insulator. To address this problem, we will tune the parameters of the lattice model discussed in Section “Dirac fermions and topological insulators,” the phase ϕ and the ratio of hopping amplitudes t_2/t_1 , to the point at which the mass of one of the two species of Dirac fermions, say the fermion ψ_1 , is zero, $m_1 = 0$, while keeping the fermion ψ_2 massive, $m_2 \neq 0$. In the low-energy regime we have a massless fermion and a massive fermion. This point in parameter space is a quantum phase transition between a trivial insulator and a Chern insulator. In the low-energy regime, the fermion ψ_1 is massless. A massless fermion is a scale-invariant system in the sense that the correlators of all its observables exhibit power law behavior (free field in this case).

We will now discuss briefly the electromagnetic response of this system at the quantum phase transition where one fermion becomes massless. In particular, it is natural to ask if the coefficient of the parity-odd (Chern–Simons) term nonvanishing at the quantum phase transition. To answer this question, we will look at the behavior of the parity-even kernel $\Pi_0(p^2)$ and the parity-odd kernel $\Pi_A(p^2)$ in the massless limit for the light fermion, $m_1 \rightarrow 0$. We find that the total contribution of both the light fermion and the heavy fermion to the polarization kernels is (assuming $m_2/m_1 \rightarrow \infty$)

$$\lim_{m_1 \rightarrow 0} \Pi_0(p^2) = \frac{i}{16\sqrt{p^2}}, \quad \lim_{|m_2| \rightarrow \infty} \Pi_A(p^2) = -\frac{1}{4\pi} \text{sgn}(m_2). \quad (338)$$

The important conclusion is that at this quantum critical point, the parity-even kernel $\Pi_0(p^2)$ is *nonlocal* and that the heavy regulator fermion (the “doubler”) yields the leading finite nonvanishing and local contribution to the parity-odd kernel $\Pi_A(p^2)$.

We can now use these results to compute the conductivity *tensor* σ_{ij} at the quantum critical point where $m_1 \rightarrow 0$. Since the system is spatially isotropic, the conductivity tensor has the form

$$\sigma_{ij} = \begin{pmatrix} \sigma_{xx} & \sigma_{xy} \\ -\sigma_{xy} & \sigma_{xx} \end{pmatrix} \quad (339)$$

where we used that $\sigma_{yy} = \sigma_{xx}$ since the system is isotropic. The *longitudinal* conductivity σ_{xx} and the Hall conductivity σ_{xy} are

$$\sigma_{xx} = \frac{\pi e^2}{8h}, \quad \sigma_{xy} = \pm \frac{1}{2} \frac{e^2}{h}. \quad (340)$$

In other words, *at* the quantum critical point the system has a finite (and universal) longitudinal conductivity. This result may seem surprising as there is no disorder in this model. A finite universal longitudinal conductivity is a standard occurrence in 2D systems at a quantum critical point. For example, at the superconductor–insulator transition, the conductivity is (conjectured to be) $\sigma_{xx} = e^2/2h$ (with $\sigma_{xy} = 0$). In addition, it also has finite and universal Hall conductivity. The Hall conductivity at the quantum critical point is due to the heavy fermionic “doubler” and is equal to $1/2$ (in units of e^2/h). So, the quantum critical point is not time-reversal invariant since this symmetry is broken at the UV (lattice).

We can examine the massless theory using a more formal approach (Witten, 2016; Seiberg et al., 2016). In a gauge-invariant regularization of the massless theory the partition function of a Dirac fermion coupled to a background (unquantized) $U(1)$ gauge field, the partition function is not time-reversal invariant. It is given by

$$Z[A_\mu] = \int \mathcal{D}\bar{\psi} \mathcal{D}\psi \exp\left(i \int d^3x \bar{\psi} i \mathcal{D}[A_\mu] \psi\right) = \det(i \mathcal{D}[A_\mu]) = |\det(i \mathcal{D}[A_\mu])| \exp\left(\pm i \frac{\pi}{2} \eta[A_\mu]\right) \quad (341)$$

where the sign depends on how time-reversal invariance is broken by the choice of regularization. The quantity $\eta[A_\mu]$ that appears in the phase factor is the Atiyah-Patodi-Singer η -invariant (Atiyah et al., 1975) which we already encountered in the discussion of the fractionally charged solitons in Section “Fractionally charged solitons.” With some caveats (Witten, 2016; Seiberg et al., 2016), the phase factor of the partition function of Eq. (341) is commonly written in the form of a $1/2$ -quantized Chern–Simons term

$$\frac{\pi}{2} \eta[A_\mu] \equiv \pm \frac{1}{2} \int d^3x \frac{1}{4\pi} \epsilon_{\mu\nu\lambda} A^\mu \partial^\nu A^\lambda \quad (342)$$

often denoted as a $U(1)_{1/2}$ Chern–Simons term. This term plays the same role as the contribution of the heavy fermion doubler in the lattice theory.

However, we can also wonder if there is a way to have a time-reversal invariant theory of a *single* massless Dirac fermion, $m \rightarrow 0$. This case cannot be realized in a 2D lattice model but, as will see, it can be realized on the surface states of a 3D time-reversal invariant $\mathbb{Z}_2$ topological insulator, which we will discuss in Section “Topological insulators.”

Three-dimensional $\mathbb{Z}_2$ topological insulators

The classification of topological insulators in terms of a Chern number is only possible in even space dimensions in systems with broken time reversal symmetry: in $d = 2$, the Berry connection is Abelian and the topological invariant is the first Chern number while in $d = 4$, the Berry connection in a non-Abelian $SU(2)$ gauge field and the topological invariant is the second Chern number (Qi et al., 2008), etc. We will now discuss the time-reversal invariant topological insulators (Fu and Kane, 2007; Moore and Balents, 2007; Qi et al., 2008) and, in particular, those that are invariant under inversion symmetry. Such states exist in both two and space dimensional insulator with strong spin-orbit coupling.

$\mathbb{Z}_2$ Topological invariants

Let $\{|u_n(\mathbf{k})\rangle\}$ be the Bloch states. We will represent time reversal by the antiunitary operator Θ that acts on the single particle (Bloch) states by complex conjugating the state and reversing the spin. For spin-1/2 fermions $\Theta = \exp(i\pi\sigma_2)\mathcal{K}$, where $\mathcal{K}$ is the complex conjugation operator. In this case, $\Theta^2 = -1$. Let us assume that we have two occupied Bloch bands for each point $\mathbf{k}$ of the Brillouin zone. In this case, the states form a rank-2 vector bundle over the torus of the Brillouin zone. In time-reversal invariant systems, the antiunitary time reversal transformation $\mathcal{T}$ induces an involution in the Brillouin zone that identifies the points $\mathbf{k}$ and $-\mathbf{k}$. Time reversal acts on the one-particle (Bloch) Hamiltonian as $\Theta H(\mathbf{k}) \Theta^{-1} = H(-\mathbf{k})$. The states $|u_n(\pm\mathbf{k})\rangle$ are related by time reversal as $|u_n(-\mathbf{k})\rangle = \Theta |u_n(\mathbf{k})\rangle$, which implies that the bundle is real. The condition $\Theta^2 = -1$ implies that the bundle is real. In algebraic topology, these bundles are classified by an integer (here the number of occupied bands) and a $\mathbb{Z}_2$ index that will allow us to classify these states.

In a periodic lattice, there exists a set of points $\mathbf{Q}_i$ of the Brillouin zone with the property that they differ by their images under the action of time reversal by a reciprocal lattice vector, $-\mathbf{Q}_i = \mathbf{Q}_i + \mathbf{G}$. In $d = 2$, there are four such points and $d = 3$, there are eight points, and are given by $\mathbf{Q}_i = \frac{1}{2} \sum_j n_j \mathbf{b}_j$, where $n_j = 0, 1$, $j = 1, 2$ in $d = 2$ and $j = 1, 2, 3$ in $d = 3$. Here, $\mathbf{b}_j$ are the primitive lattice

vectors. Kane and Mele (2005) defined the $2N \times 2N$ antisymmetric matrix $w_{m,n}(\mathbf{k}) = \langle u_m(-\mathbf{k}) | \Theta | u_n(\mathbf{k}) \rangle$. They showed that at each time-reversal invariant point Q_i , one can define an index δ_i

$$\delta_i = \frac{\sqrt{\det[w(Q_i)]}}{\text{Pf}[w(Q_i)]} = \pm 1 \quad (343)$$

where $\det[w]$ and $\text{Pf}[w]$ are, respectively, the determinant and the Pfaffian of the matrix w , and $\det[w] = \text{Pf}[w]^2$. The sign of the quantities δ_i can be made unambiguous by requiring that the Bloch states be continuous. In addition, the quantities δ_i are gauge-dependent. However the products

$$(-1)^v = \prod_{i=1}^4 \delta_i \quad (344)$$

in $d = 2$, and

$$(-1)^{v_0} = \prod_{i=1}^8 \delta_i, \quad (-1)^{v_k} = \prod_{n_k=1, n_{j \neq k}=0,1} \delta_i(n_1, n_2, n_3) \quad (345)$$

are gauge and are also topological invariant. The $\mathbb{Z}_2$ -valued indices v and v_0 are robust to disorder and are called strong topological indices. Furthermore, Fu and Kane showed that if $\zeta_n(Q_i) = \pm 1$ are the parity eigenvalues of the occupied parity eigenstates, the quantities δ_i are given by $\delta_i = \prod_{m=1}^N \zeta_{2m}(Q_i)$. In $d = 3$, the index v_0 does not rely on the existence of inversion symmetry.

In the case of a two-band model in $d = 2$ and in $d = 3$, the states are four-component spinors reflecting the two bands and the two spin components. In the context of these systems with strong spin-orbit coupling spin is actually the z -component of the atomic total angular momentum J of the electrons with energies close to the Fermi energy. In these systems, the one-particle Hamiltonian $H(\mathbf{k})$ is a 4×4 Hermitian matrix, which can be expanded as a linear combination of Dirac matrices. A simple and very useful model of systems of this type is the Wilson fermion model (with continuous time) (Wilson, 1974; Bernevig et al., 2006; Qi et al., 2008) of a square (cubic) lattice with 4 states per site (parity and spin) whose Hamiltonian in three dimensions is

$$H(\mathbf{k}) = \sin \mathbf{k} \cdot \boldsymbol{\alpha} + M(\mathbf{k}) \beta \quad (346)$$

where $\boldsymbol{\alpha} = \gamma_0 \boldsymbol{\gamma}$ and $\beta = \gamma_0$ are the conventional 4×4 Dirac matrices. The γ matrices satisfy the Clifford algebra $\{\gamma_\mu, \gamma_\nu\} = 2g_{\mu\nu} \mathbf{1}$, where $g_{\mu\nu} = \text{diag}(1, -1, -1, -1)$ is the metric tensor of four-dimensional Minkowski space time. An additional γ matrix of interest is $\gamma_5 = i\gamma_0\gamma_1\gamma_2\gamma_3$.

The (Wilson) mass term $M(\mathbf{k})$ in two dimensions is $M(\mathbf{k}) = M + \cos k_1 + \cos p_2 - 2$, and in three dimensions is $M(\mathbf{k}) = M + \cos k_1 + \cos k_2 + \cos k_3 - 3$. In Eq. (346), we see that, consistent with the requirements of the Nielsen–Ninomiya theorem (Nielsen and Ninomiya, 1981a,b), in addition to a possible low energy Dirac fermion (if M is small), there are three more massive Dirac fermions (in $d = 2$) and seven other Dirac fermions in $d = 3$ so that the total number of Dirac fermions is always even, 8 in this case. With Wilson’s mass term, the additional Dirac fermions (the “doublers”) are always heavy even if the Dirac fermion near the Γ point $Q = 0$ is light.

In the Dirac basis time reversal is the operation $\Theta = (i\sigma_2 \otimes I)\mathcal{K}$, where $\mathcal{K}$ is complex conjugation and parity is $P = \beta$. The matrices $\boldsymbol{\alpha}$ and β commute with $P\Theta$. At the time-reversal and parity invariant points of the Brillouin zone $\{Q_i\}$, the Hamiltonian only depends on the matrix β , $H(Q_i) = M(Q_i)\beta$. Since the parities of the spinors are the eigenvalues of the matrix β , we conclude that in the two-band models, the quantities δ_i are simply equal to the sign of the mass of the fermions defined at the time-reversal-invariant points Q_i of the BZ (Fu and Kane, 2007; Qi et al., 2008), $\delta_i = \delta(Q_i) = -\text{sgn } M(Q_i)$. Using this result, it follows that in two dimensions the system is a $\mathbb{Z}_2$ topological insulator with index $v = 1 \pmod{2}$ if $0 < M < 4$ while it is trivial for other values of M , that is, $v = 0 \pmod{2}$. Similarly, in three dimensions, a $\mathbb{Z}_2$ (strong) topological insulator exists only if $0 < M < 2$ (in the other regimes, this system is in a weak topological insulator state or in a trivial one).

We conclude that both in two and three dimensions, the low energy theory of the $\mathbb{Z}_2$ topological insulators consists of a single Dirac fermion whose mass is small compared to that of the fermion doublers and has the opposite sign. In both cases, there is a quantum phase transition between a trivial insulator and the time-reversal invariant topological insulator at the point where the mass of the light fermion vanishes.

The axial anomaly and the effective action

We will now look at the electromagnetic response of a $\mathbb{Z}_2$ topological insulator in 3+1 dimensions. This problem can be addressed more easily using the continuum field theory description, which is valid in the regime where the mass M is weak. In this regime, one species of Dirac fermions is light (i.e., its mass is small) while the Dirac doublers remain heavy. Much as we did in our discussion of the Chern insulators and the *parity anomaly* in Section “The parity anomaly,” we will keep in mind that the fermion doublers play the role of heavy regulators, such as in the Pauli–Villars scheme, in Quantum Field Theory. Here too, we will see that a field-theoretic anomaly, known as the *axial anomaly*, plays a central role in the physics. The analysis is very similar to what we did with the *chiral anomaly* in 1+1 dimensions in Section “The chiral anomaly.”

Let us begin with a theory of a single massive Dirac fermion in 3+1 dimensions. The Lagrangian of the free massive Dirac theory is

$$\mathcal{L} = \bar{\psi} (i\partial - m)\psi. \quad (347)$$

The equation of motion of the spinor field operator $\psi(x)$ (I omit the spinor indices here) is the Dirac equation

$$(i\partial - m)\psi = 0. \quad (348)$$

The Dirac Lagrangian has a global gauge symmetry $\psi \rightarrow e^{i\theta}\psi$, which requires that the Dirac current $j_\mu = \bar{\psi}\gamma_\mu\psi$ is locally conserved, $\partial_\mu j^\mu = 0$. The *massless* Dirac theory can be decomposed into a theory of two Weyl bi-spinor fields that obey separate Dirac Lagrangians. Furthermore, the massless theory has the additional global symmetry under the transformation $\psi \rightarrow e^{i\theta\gamma_5}\psi$ and the additional formally locally conserved *axial* current $j_\mu^5 = i\bar{\psi}\gamma_\mu\gamma_5\psi$. However the conservation law of the axial current is violated in the *massive* Dirac theory

$$\partial^\mu j_\mu^5 = -2mi\bar{\psi}\gamma_5\psi \quad (349)$$

since the two Weyl bi-spinors transmute into each other in the presence of a mass term. This is the origin of the phenomenon of neutrino oscillations. In the condensed matter physics, context there is a similar phenomenon in systems of Weyl semimetals which have crossings between the valence and conducting bands at two locations $\pm Q$ of the BZ, with each crossing associated with each Weyl bi-spinor. A charge density wave with ordering wavevector $2Q$ mixes the two Weyl fermions that become gapped, becoming effectively a single massive Dirac fermion (Gooth et al., 2019). This state is often called an “axionic”-charge-density-wave.

We will now show that the axial symmetry has an anomaly and cannot be gauged. Thus, we will consider the problem of a Dirac theory coupled to a background $U(1)$ gauge field A_μ and reexamine the putative conservation of the axial current j_μ^5 . This question can be addressed in different ways. Quite early on Adler (1969), and Bell and Jackiw (1969) examined this problem by computing a Dirac fermion triangle diagram for the process of a neutral pion decaying into two photons, $\pi^0 \rightarrow 2\gamma$. In particle physics, the pion is the Goldstone boson of the spontaneously broken chiral symmetry. The analog of this problem in condensed matter physics is the phase mode of an incommensurate charge density wave. The relativistic Lagrangian for this problem is a theory of Dirac fermions coupled to a complex scalar field $\phi = \phi_1 + i\phi_2$ through two Yukawa couplings

$$\mathcal{L} = \bar{\psi}i\partial\psi + g\phi_1\bar{\psi}\psi + ig\phi_2\bar{\psi}\gamma_5\psi - V(\phi_1, \phi_2) = \bar{\psi}i\partial\psi + g|\phi|\bar{\psi}e^{i\gamma_5\theta}\psi - V(|\phi|^2) \quad (350)$$

where $|\phi|^2 = \phi_1^2 + \phi_2^2$, $\tan \theta = \phi_2/\phi_1$, and $D_\mu = \partial_\mu + ieA_\mu$ is the covariant derivative. Here we are regarding the gauge field A_μ as a background probe field.

The triangle Feynman diagram computes the polarization tensor for the electromagnetic field A_μ with an insertion of the coupling to the complex scalar field in an otherwise massless theory. Assuming a gauge-invariant regularization of the diagram, this computation finds that the axial current j_μ^5 is anomalous and is not conserved even in the massless theory (Adler, 1969; Bell and Jackiw, 1969)

$$\partial^\mu j_\mu^5 = -\frac{e^2}{16\pi^2} F^{\mu\nu} F_{\mu\nu}^* \quad (351)$$

where $F_{\mu\nu}^* = \frac{1}{2}\epsilon_{\mu\nu\lambda\rho}F^{\lambda\rho}$ is the dual of the electromagnetic field tensor. This is the *axial anomaly*.

To see how the axial anomaly arises, we will follow the physically transparent approach of Nielsen and Ninomiya (1983), which we also employed in Section “The chiral anomaly” in 1+1 dimensions. We will consider a theory of free massless Dirac fermions coupled to a background electromagnetic field. Since the theory is massless, the Dirac equation decouples into an equation to the right-handed Weyl fermion ψ_R (with positive chirality $\gamma_5\psi_R = +\psi_R$) and a left-handed Weyl fermion ψ_L (with negative chirality, $\gamma_5\psi_L = -\psi_L$). In the gauge $A_0 = 0$, the Dirac equations become

$$[i\partial_0 - (-i\partial - e\mathbf{A}) \cdot \boldsymbol{\sigma}]\psi_R = 0, \quad [i\partial_0 - (i\partial - e\mathbf{A}) \cdot \boldsymbol{\sigma}]\psi_L = 0 \quad (352)$$

Let us now consider looking at the solutions of the Weyl equation for right-handed fermions ψ_R , Eq. (352). The left-handed fermions ψ_L are analyzed similarly. We will consider a gauge field $A_1 = 0$ and $A_2 = Bx_1$ representing a uniform static magnetic field of strength B pointing along the x_3 direction. In this gauge, the eigenstates are plane waves along the directions x_2 and x_3 and harmonic oscillator states along the direction x_1 . The eigenvalue spectrum consists of Landau levels with energies

$$E(n, p_3, \sigma_3) = \pm \left[2eB \left(n + \frac{1}{2} \right) + p_3^2 + eB\sigma_3 \right]^{1/2} \quad (353)$$

for $n = 0, 1, 2, \dots$, except for the *zero mode* with $n = 0$ and $\sigma_3 = -1$, for which

$$E(n = 0, p_3, \sigma_3 = -1) = \pm p_3 \quad (354)$$

where the + sign holds for ψ_R and the – sign for ψ_L . Just as in the case of nonrelativistic fermions, the relativistic Landau levels are degenerate. We will consider a system of Dirac fermions at charge neutrality and, hence, $E_F = 0$. The positive and negative energy states are charge conjugate of each other and the negative energy states are filled. For right-handed fermions, the zero mode states with $p_3 < 0$ are filled while for right-handed states the zero modes with $p_3 > 0$ are filled. The density of states of the zero modes is $LeB/(4\pi^2)$ (where L is the linear size of the system).

Let us consider now turning on an external electric field E *parallel* to the magnetic field B . Just as we saw in 1+1 dimensions in Section “The chiral anomaly,” the electric field leads to pair creation by shifting the Fermi momentum to p_F for the zero modes. There is no particle creation for the states with $n \neq 0$ and they do not contribute to the anomaly. The rate of creation of right-handed fermions, N_R is

$$\frac{dN_R}{dx_0} = \frac{1}{L} \frac{LeB}{4\pi^2} \frac{p_F}{dx_0} = \frac{e^2}{4\pi^2} EB. \quad (355)$$

The annihilation rate of left-handed particles is

$$\frac{dN_L}{dx_0} = -\frac{1}{L} \frac{LeB}{4\pi^2} \frac{p_F}{dx_0} = -\frac{e^2}{4\pi^2} EB \quad (356)$$

and the creation rate of left-handed antiparticles is

$$\frac{d\bar{N}_L}{dx_0} = \frac{1}{L} \frac{LeB}{4\pi^2} \frac{p_F}{dx_0} = \frac{e^2}{4\pi^2} EB. \quad (357)$$

The axial anomaly is the total rate of creation of right-handed particles and of left-handed antiparticles:

$$\frac{dQ_5}{dx_0} = \frac{dN_R}{dx_0} + \frac{d\bar{N}_L}{dx_0} = \frac{e^2}{2\pi^2} EB \quad (358)$$

which agrees with the expression of Eq. (351).

We now turn to the $\mathbb{Z}_2$ topological insulator. As we saw, this is a system with two species of (4 component) Dirac spinors. In the topological phase, the sign of the Dirac mass term one of the Dirac fermions (the one near the Γ point in the lattice model) is opposite (negative) to the sign of the mass term of the other Dirac fermion (the fermion doubler). Explicit calculations (Qi et al., 2008; Essin et al., 2009; Hosur et al., 2010) on the lattice model obtain the result that the effective low-energy action for the electromagnetic gauge field A_μ in the topological phase is

$$S_{\text{eff}}[A_\mu] = \int d^4x \left[-\frac{1}{4e^2} F_{\mu\nu} F^{\mu\nu} + \frac{\theta}{32\pi^2} e^2 \epsilon_{\mu\nu\lambda\rho} F^{\mu\nu} F^{\lambda\rho} \right] + \dots \quad (359)$$

In a time-reversal invariant system, the allowed values of the θ angle of Eq. (359) are restricted to be $\theta = n\pi$, with $n \in \mathbb{Z}$. The case $\theta = 0 \pmod{2\pi}$ represents a trivial insulator, whereas $\theta = \pi \pmod{2\pi}$ holds for a $\mathbb{Z}_2$ time-reversal invariant topological insulator.

The second term in the effective action of the electromagnetic gauge field of Eq. (359), known as the θ term, has been extensively discussed in the high-energy physics literature (Fujikawa, 1979; Wilczek, 1987; Peskin and Schroeder, 1995). The derivation of this term is subtle. As it stands, unless θ is varying in space-time (in which case this is known as the axion field), this term is a total derivative. In non-Abelian Yang–Mills gauge theories, this term is proportional to a topological invariant known as the Pontryagin index which counts the instanton number of the gauge field configurations (Callan et al., 1976; Coleman, 1985). In the context of the Lagrangian of Eq. (350), this term is induced by the coupling of the Dirac fermion to the Yukawa coupling of the complex scalar field ϕ to the Dirac and γ_5 mass terms. In this case, the lowest order contribution is given by the triangle diagram. The fact that this term is exact at lowest order reflects the fact that the axial anomaly is in fact a nonperturbative effect, which is the same in both the weak coupling and the strong coupling regimes (’t Hooft, 1976b).

In the phase where the potential $V(|\phi|^2)$ in the Lagrangian of Eq. (171) has a minimum at $|\phi_0| \exp(i\theta)$, the chiral symmetry is spontaneously broken and the phase field $\theta(x)$ is the Goldstone boson of the spontaneously broken chiral symmetry. In this phase, the Dirac fermions become massive through the Yukawa couplings to the complex scalar field, and the phase of the field ϕ enters in the effective action as an axion field which couples to the gauge field A_μ through the θ term of the effective action. We should note that in a recently studied axionic CDW state of a Weyl semimetal (Gooth et al., 2019), the phase of the CDW plays the role of the axion field.

Theta terms, and domain walls: Anomaly and the Callan–Harvey effect

We will now discuss some remarkable behaviors of three-dimensional $\mathbb{Z}_2$ topological insulators. We will begin with the electromagnetic response encoded in the effective action of Eq. (359). We will assume that the θ angle is effectively a slowly varying Goldstone mode of the spontaneously broken $U(1)$ chiral symmetry (i.e., the axion field) present in the Lagrangian of Eq. (350). If the field θ is constant, the θ term will be a total derivative and it will not contribute to the local equations of motion. We will see below that this term plays a key role in the physics of a domain wall, which we will regard as the interface of a $\mathbb{Z}_2$ topological insulator and a trivial insulator. In the general case in which θ varies slowly (as Goldstone modes do), its presence leads to interesting modification of Maxwell’s equations, known as axion electrodynamics (Wilczek, 1987):

$$\begin{aligned} \nabla \cdot \mathbf{E} &= \tilde{\rho} - e^2 \nabla \theta \cdot \mathbf{B}, & \nabla \times \mathbf{E} &= -\partial_t \mathbf{B} \\ \nabla \times \mathbf{B} &= \partial_t \mathbf{E} + \tilde{\mathbf{j}} + e^2 (\partial_t \theta + \nabla \theta \times \mathbf{E}), & \nabla \cdot \mathbf{B} &= 0 \end{aligned} \quad (360)$$

where $\tilde{\rho}$ and $\tilde{\mathbf{j}}$ are external probe electric charge and current densities. The equations of axion electrodynamics have many remarkable properties. Here we will focus on effects: the topological magnetoelectric effect (Qi et al., 2008) and the Witten effect (Witten, 1979).

Let us consider a $\mathbb{Z}_2$ topological insulator with a flat open boundary (the $x_1 - x_2$ plane) perpendicular to the direction x_3 . We will assume that the topological insulator lies at $x_3 < 0$. This means that for $x_3 < 0$, and far from the surface, $\theta(x_3) \rightarrow \pi$, while in the trivial vacuum, and also far from the surface, $\theta(x_3) \rightarrow 0$. We will assume that the change of θ from 0 to π occurs on a short distance ξ . We will call this configuration an axion domain wall. In the region where $\theta(x_3)$ is changing, $|x_3| \lesssim \xi$, an applied uniform magnetic field $\mathbf{B}$ induces a uniform electric field $\mathbf{E}$ parallel to $\mathbf{B}$ whose magnitude is proportional to the change in θ . This is the topological magnetoelectric effect (Qi et al., 2008).

A similar striking effect is obtained by considering the case of a magnetic monopole of magnetic charge $2\pi/e$ (as required by Dirac quantization) inside a sphere of the trivial region of radius R , with $\theta = 0$, surrounded by a region with $\theta \neq 0$. The two regions are separated by a thin (axion) wall in which θ changes for 0 to π in a narrow shell of thickness $\xi \ll R$. The equations of axion electrodynamics imply that the magnetic monopole induces an electric charge Q_e on the surface of the sphere

$$Q_e = e \frac{\Delta\theta}{2\pi}. \quad (361)$$

Thus, a magnetic monopole acquires an electric charge and becomes a *dyon*. This is the Witten effect (Witten, 1979). In the particular case of a $\mathbb{Z}_2$ topological insulator, time-reversal invariance requires that $\Delta\theta = \pi$, which implies that a monopole with unit magnetic charge has an electric charge $e/2$. A similar argument implies that an external magnetic field perpendicular to the open surface of the $\mathbb{Z}_2$ topological insulator (which is essentially an axion domain wall) induces an *electric charge polarization* on the surface proportional to the total magnetic flux, which is another manifestation of the topological magnetoelectric effect.

The reader should readily recognize that the result of Eq. (361) for the electric charge induced by the magnetic monopole is the same as the Goldstone–Wilczek equation for the fractional charge for a one-dimensional soliton of Eq. (215). We will now see that this is not just an analogy. We will follow here the general approach of Callan and Harvey (1985) who extended the earlier work of Goldstone and Wilczek (1981). Let us consider the bulk of a $\mathbb{Z}_2$ topological insulator and assume that $\theta(x)$ is slowly varying. We can use the triangle diagram calculation to find that an electromagnetic gauge field A_μ induces a current $\langle J_\mu(x) \rangle$ given by

$$\langle J_\mu(x) \rangle = -i \frac{e}{16\pi^2} \epsilon_{\mu\nu\lambda\rho} \frac{\phi^*(x) \partial^\nu \phi(x) - \phi(x) \partial^\nu \phi^*(x)}{|\phi(x)|^2} F^{\lambda\rho}(x) = \frac{e}{8\pi^2} \epsilon_{\mu\nu\lambda\rho} \partial^\nu \theta(x) F^{\lambda\rho}(x) \quad (362)$$

This result implies that, in the case of a domain wall in the $x_1 - x_2$ plane, a magnetic field perpendicular to the wall induces a current toward the wall and, hence, a charge accumulation on the wall. Where does this charge come from? To understand this problem, we will consider a $\mathbb{Z}_2$ topological insulator occupying a slab of macroscopic size L between a wall at $x_3 = 0$ and a far away “anti-wall” at $x_3 = L$. In this configuration, a magnetic field normal to the wall(s) induces a transfer of charge from one wall to the other. Similarly, an electric field *parallel* to the wall induces a current also parallel to the wall and *perpendicular* to the electric field, that is, a Hall current.

In 1+1 dimensions, we saw that soliton configurations acquire a fractional charge associated to states bound to the soliton (which are zero modes when $\Delta\theta = \pi$). We will see that the surfaces of the 3D $\mathbb{Z}_2$ topological insulators also have zero modes which are Weyl fermions propagating on the wall. To see how this works, we will consider a 3+1 dimensional Dirac fermion with a Dirac mass that changes sign at $x_3 = 0$. The Lagrangian now will be

$$\mathcal{L} = \bar{\psi} i \not{\partial} \psi + g \phi(x) \bar{\psi} \psi \quad (363)$$

where $\phi(x)$ is now a *real* scalar field that has the asymptotic behaviors $\phi(x_3) = \phi_0 f(x_3)$ such that $\lim_{x_3 \rightarrow \pm\infty} f(x_3) = \pm 1$. We will assume that $f(x_3)$ is a monotonous function of x_3 , but its actual dependence on x_3 is immaterial aside from the requirement that it should change sign at some point which we will take to be $x_3 = 0$. This is a special case of Eq. (350) with $\phi_1 = \phi$ and $\phi_2 = 0$. We will now recognize that this is just a Dirac fermion with a position-dependent Dirac mass $m(x_3) = g\phi(x_3)$. The one-particle Dirac Hamiltonian for this system is

$$H = -i\boldsymbol{\alpha} \cdot \nabla + m(x_3)\beta \quad (364)$$

where $\boldsymbol{\alpha}$ and β are the four 4×4 Dirac matrices. By symmetry, this Hamiltonian can be split into two Hamiltonians, $H = H_{\text{wall}} + H_{\perp}$,

$$H_{\text{wall}} = -i\alpha_1 \partial_1 - i\alpha_2 \partial_2, \quad H_{\perp} = -i\alpha_3 \partial_3 + m(x_3)\beta. \quad (365)$$

Let the spinor $\psi_{\pm}$ be an eigenstate of the anti-Hermitian Dirac matrix $\gamma_3 = \beta\alpha_3$ with eigenvalues $\pm i$, respectively

$$\gamma_3 \psi_{\pm} = \pm i \psi_{\pm}. \quad (366)$$

We seek a spinor solution $\psi_{\pm}$ of the Dirac equation (Eq. 364) such that $H_{\perp} \psi_{\pm} = 0$

$$\pm \partial_3 \psi_{\pm} + m(x_3) \psi_{\pm} = 0 \quad (367)$$

which is also a solution of

$$(i\gamma_0 - i\gamma_1 \partial_1 - i\gamma_2 \partial_2) \psi_{\pm} = 0. \quad (368)$$

In other words, it is a solution of the massless Dirac equation in 2+1 dimensions. The requirement that $\psi_{\pm}$ is an eigenstate of γ_3 reduces the number of spinor components from four to two. The full solution has the form

$$\psi_{\pm} = \eta_{\pm}(x_0, x_1, x_2)F_{\pm}(x_3), \quad \pm \partial_3 F_{\pm}(x_3) = -m(x_3)F_{\pm}(x_3). \quad (369)$$

For a domain wall with $\lim_{x_3 \rightarrow \infty} m(x_3) = +m$, the normalizable solution of $F_+(x_3)$ is

$$F_+(x_3) = F(0) \exp\left(-\int_0^{\infty} dx'_3 m(x'_3)\right) \quad (370)$$

where $F(0)$ is a constant. For the antidomain wall, for which $\lim_{x_3 \rightarrow \infty} m(x_3) = -m$, the normalizable solution is $F_-(x_3)$.

We conclude that there is a 2+1-dimensional massless Dirac theory that describes the quantum states bound to the wall, which propagate along the wall. These states are the generalization of the fractionally charged midgap states of solitons in one dimension discussed in Section “Fractionally charged solitons.” The energy of these states is $E(\mathbf{p}) = \pm|\mathbf{p}|$, where $\mathbf{p} = (p_1, p_2)$ (where I set the Fermi velocity to unity). Experimental evidence for 2+1 dimensional massless Dirac fermions on the surface of the 3D $\mathbb{Z}_2$ topological insulator Bi_2Te_3 has been found in spin-polarized angle-resolved photoemission studies of the surface states, which showed that they have a linear energy-momentum relation (expected of massless Dirac fermions) as well as the spin-momentum locking characteristic of these spinor states (Hsieh et al., 2009).

Having succeeded in showing that the surface of the $\mathbb{Z}_2$ time-reversal invariant 3D topological insulator has a two-component massless Dirac spinor, we now want to determine its electromagnetic response. In fact we have already discussed this problem in our discussion of the parity anomaly in Section “The parity anomaly” where we showed that the effective action for the electromagnetic field A_{μ} of Eq. (342) of a single massless Dirac bi-spinor is a Chern–Simons term with a prefactor, which is 1/2 of the allowed value. In that purely 2+1-dimensional context we saw that time-reversal invariance is actually broken. However, the 3D problem is time-reversal invariant so there must be a contribution that cancels this time-reversal anomaly. The answer is that the requisite cancellation is supplied by the bulk.

To see how this can happen, we return to the bulk effective action of the 3D topological insulator of Eq. (359) where we observed that the θ term is a total derivative. Suppose that the system has a boundary at $x_3 = 0$ and that the topological insulator exists for $x_3 > 0$ (where the fermion mass is negative, $m < 0$) and trivial for $x_3 < 0$ (where $m > 0$). Only the region with $m < 0$ contributes to the θ term. The region of four-dimensional space time occupied by the topological insulator is $\mathcal{M}$ and in this region the θ term becomes

$$S_{\theta}[A] = \frac{\theta}{32\pi^2} \int_{\mathcal{M}} d^4x \epsilon_{\mu\nu\lambda\rho} F^{\mu\nu} F^{\rho\lambda} = \frac{\theta}{8\pi^2} \int_{\mathcal{M}} d^4x \epsilon_{\mu\nu\lambda\rho} \partial^{\mu} A^{\nu} \partial^{\lambda} A^{\rho} = \frac{\theta}{8\pi^2} \int_{\partial\mathcal{M}} d^3x \epsilon_{\mu\nu\lambda} A^{\mu} \partial^{\nu} A^{\lambda} \quad (371)$$

where $\partial\mathcal{M} \equiv \Sigma \times \mathbb{R}$ is the boundary of the region $\mathcal{M}$, Σ is the surface of the 3D topological insulator, and $\mathbb{R}$ is time.

Thus we see that the θ term of the effective action $S_{\theta}[A]$ integrates to the boundary where it has the form of a 2+1-dimensional Chern–Simons term. Since for a time-reversal-invariant 3D topological insulator $\theta = \pi$, we see that in this case the boundary Chern–Simons term becomes

$$S_{\theta=\pi}[A] = \frac{1}{8\pi} \int_{\partial\mathcal{M}} d^3x \epsilon_{\mu\nu\lambda} A^{\mu} \partial^{\nu} A^{\lambda} \quad (372)$$

with a coefficient which is 1/2 of the allowed value. This bulk contribution cancels the parity anomaly of the boundary state, rendering the full system time-reversal invariant. In other words, in this system, time-reversal symmetry is realized by cancellation of the anomaly between the bulk of the topological insulator and the boundary or, equivalently, by an *inflow* of the parity anomaly between the boundary and the bulk of the system. Another way to phrase this result is the statement that a single Dirac fermion cannot exist on its own in 2+1 dimensions but it can as the boundary state of a 3+1-dimensional system whose anomaly cancels the anomaly of the boundary.

Chern–Simons gauge theory and the fractional quantum Hall effect

We will now turn to the problem of the quantum Hall effects. This is a problem that revealed the existence of profound and far-reaching connections between condensed matter physics, quantum field theory, CFT, and topology. In particular, the *fractional* quantum hall effect is the best studied and best understood topological phase of matter. As such, it has become the conceptual springboard for its manifold generalizations.

The integer (IQHE) and fractional (FQHE) quantum Hall effects are fascinating phenomena observed in fluids of electrons in two dimensions in strong perpendicular magnetic fields. The integer quantum Hall effect was discovered by von Klitzing et al. (1980) in transport measurements of the longitudinal and Hall resistivity of the surface states of metal oxide field-effect transistors (MOSFET) in magnetic field of up to 15 Tesla. The effect that von Klitzing discovered (for which he was awarded the 1985 Nobel Prize in Physics) was that in the high-field regime the measured Hall conductivity showed a series of sharply defined plateaus at which took the values $\sigma_{xy} = ne^2/h$, where n is an integer, and the longitudinal conductivity appeared to vanish $\sigma_{xx} \rightarrow 0$ as the temperature was lowered down to $T \simeq 1.5$ K. Remarkably the measured value of the Hall conductivity was obtained with a precision of $\sim 10^{-9}$. To this date, the measurement of the Hall conductivity in the IQHE yields the most precise definition of the fine structure constant.

Subsequent transport experiments in ultra-high-purity GaAs-AlAs heterostructures by Dan Tsui, Horst Störmer, and Art Gossard found that, in addition to the IQHE, two-dimensional electron fluids in high magnetic fields exhibit the *fractional* quantum Hall effect meaning that there are equally sharply defined plateaus of the Hall conductivity at the values $\sigma_{xy} = \frac{p}{q} \frac{e^2}{h}$, where p and q are

co-prime integers (Tsui et al., 1982). Much as in the IQHE case, in the FQHE, the longitudinal conductivity vanishes at low temperatures. It is important to note that both in the IQHE and in the FQHE, the observed temperature dependence in the highest purity samples of the longitudinal conductivity is activated, $\sigma_{xx} \sim \exp(-W/T)$. The observed value of the energy scale W is the experimental estimate of an energy gap in the electron fluid in the quantum Hall states.

In addition to MOSFETS and GaAs-AlAs, heterostructures, both the IQHE and the FQHE, have been seen in several other experimental platforms, particularly in graphene and other 2D materials (Du et al., 2009; Zibrov et al., 2017). The explanation of these effects and of a panoply of startling consequences that were uncovered in the course of understanding this phenomenon is the focus of this section.

Landau levels and the integer Hall effect

At some level, the integer quantum Hall effect can be explained by the Landau quantization of the energy levels of a free charged moving in two dimensions in a perpendicular magnetic field (Landau, 1930). The Hamiltonian for a nonrelativistic particle of charge $-e$ and mass M in a perpendicular magnetic field B is

$$H = \frac{1}{2M} \left(-i\hbar\nabla + i\frac{e}{c}\mathbf{A}(\mathbf{x}) \right)^2 \quad (373)$$

for a uniform perpendicular magnetic field $\mathbf{B} = B\hat{\mathbf{e}}_z = \nabla \times \mathbf{A}(\mathbf{x})$.

In the circular gauge, the vector potential is $A_i = -\frac{1}{2}B\epsilon_{ij}x_j$. We will assume that the 2D plane has linear size L . The total magnetic flux is $\Phi = BL^2$ and we will assume that there is an integer number N_ϕ of magnetic flux quanta piercing the plane, $\phi = N_\phi\phi_0$, where $\phi_0 = hc/e$ is the flux quantum. In units such that $\hbar = e = c = 1$, the flux quantum is $\phi_0 = 2\pi$ and $\Phi = 2\pi N_\phi$.

In the presence of a magnetic field, the components of the canonical momentum operator $\mathbf{p} = -i\hbar\nabla - \frac{e}{c}\mathbf{A}$ do not commute with each other

$$[p_i, p_j] = i\frac{e\hbar}{c}B\epsilon_{ij}. \quad (374)$$

This means that translations in two directions do not commute with each other. However, the components of the operator $\mathbf{k} = \mathbf{p}(-B)$ commute with $\mathbf{p}$ (and hence with the one-particle Hamiltonian) but do not commute with each other: the commutator is the same as in Eq. (374). Since $[\mathbf{k}, H] = 0$, they act as symmetry generators of the group of *magnetic translations*. For arbitrary displacements $\mathbf{a}$ and $\mathbf{b}$, the translation operators $t(\mathbf{a}) = \exp(i\mathbf{a} \cdot \mathbf{k}/\hbar)$ (and similarly with $\mathbf{b}$) satisfy

$$t(\mathbf{a})t(\mathbf{b}) = \exp(i\mathbf{a} \times \mathbf{b} \cdot \mathbf{e}_z/\ell_0^2)t(\mathbf{b})t(\mathbf{a}). \quad (375)$$

Magnetic translations only commute with each other if the area subtended by $\mathbf{a}$ and $\mathbf{b}$ contains an integer number of magnetic flux quanta.

Given the rotational symmetry of the circular gauge, it is natural to work in complex coordinates $z = x_1 + ix_2$. We will also use the notation $\partial_z = (\partial_1 - i\partial_2)/2$ and $\partial_{\bar{z}} = (\partial_1 + i\partial_2)/2$. In this gauge, up to a normalization, the eigenstate wave functions have the form

$$\psi(z, \bar{z}) = f(z, \bar{z}) \exp\left(-\frac{|z|^2}{4\ell_0^2}\right) \quad (376)$$

where $\ell_0 = \sqrt{\frac{\hbar c}{e|B|}}$ is the magnetic length. In this gauge (and in complex coordinates), the angular momentum operator $L_z = -i\hbar(x_1\partial_2 - x_2\partial_1) = \hbar(z\partial_z - \bar{z}\partial_{\bar{z}})$.

Any analytic function $f(z)$ is an eigenstate with energy $E_0 = \frac{1}{2}\hbar\omega_c$. A complete basis of analytic functions are the monomials $f_n(z) = z^n$ and have energy E_0 and angular momentum $L_z = n\hbar$. This is the lowest Landau level whose wave functions are $\psi_n(z) = z^n \exp(-|z|^2/4\ell_0^2)$. On the other hand, an antianalytic function $f_N = \bar{z}^N$ is an eigenstate of energy $E_N = \hbar\omega_c(N + \frac{1}{2})$, where $\omega_c = \frac{e|B|}{Mc}$ is the cyclotron frequency, and angular momentum $L_z = -N\hbar$. States with angular momentum $n\hbar$ have the same energy, and the degeneracy is equal to the number of flux quanta N_ϕ . For the most part, we will be interested in the states in the lowest Landau level.

In the absence of disorder, the Landau levels have an extensive degeneracy equal to the number of flux quantum N_ϕ . If we consider a system of N electrons in a Landau level the natural measure of density is not the areal density $\rho = \frac{N}{L^2}$ but the fraction $\nu = \frac{N_e}{N_\phi}$ the states in the Landau level which are occupied by electrons. The many-body state in which all N_ϕ states of the lowest Landau level has filling fraction $\nu = 1$. The wave function for this state is the Slater determinant of the Landau states in the $m = 0$ level. After some simple algebra, the wave function of this state is found to be

$$\Psi_{\nu=1}(z_1, \dots, z_{N_e}) = \prod_{i < j} (z_i - z_j) \exp\left(-\sum_{i=1}^{N_e} \frac{|z_i|^2}{4\ell_0^2}\right). \quad (377)$$

This is the ground state of the noninteracting system and it is nondegenerate. It is easy to see that this state has a finite energy gap. Indeed, in the Hilbert space with a fixed number of electrons, the lowest energy excitation is a particle-hole pair in which the particle is in an unoccupied state of the first excited Landau level, with $m = 1$ and energy $E_1 = \frac{3}{2}\hbar\omega_c$ and a hole a single-particle state in the lowest Landau level, with energy $E_0 = \hbar\omega_c$. The excitation energy of the electron-hole pair is just $\hbar\omega_c$, which is finite. However, in the free particle system, this excited state has a huge degeneracy as the particle and the hole can be in any single particle state of the Landau level.

At a very naive level, one can estimate the Hall conductivity for a translationally invariant system filling up n Landau level by the following simple argument. If n Landau levels are filled, the number of electrons $N = nN_\phi$ and the total charge are then $Q = eN = e n N_\phi = e n BL^2/\phi_0 = ne^2BL^2/hc$. If a weak and uniform in-plane electric field E is applied in the presence of a perpendicular magnetic field $B = B \mathbf{e}_z$, then the entire system (its center of mass) moves at the drift velocity $\mathbf{v}$ such that $\mathbf{v} \times \mathbf{B} = -E\mathbf{e}_z$. Thus, there is a Hall current $\mathbf{J} = Q\mathbf{v}$. The current density is $\mathbf{j} = \mathbf{J}/L^2 = Q\mathbf{v}/L^2$. Hence, $j_i = \frac{Qc}{BL^2} \epsilon_{ij} E_j$, which implies that the Hall conductivity is $\sigma_{xy} = Qc/BL^2 = ne^2/h$.

While the above argument is formally correct and yields the correct value of the Hall conductivity in this highly idealized setting, at a very basic level, it is faulty. To begin with, it assumes exact translational invariance and, hence, Galilean symmetry, which are not obeyed in any realistic system. The second objection is that, even in this idealized system, as the number of electrons is varied, the chemical potential (and hence the Fermi energy) jumps discontinuously from one Landau level to the next, resulting in a linearly increasing Hall conductivity (as predicted classically) without any of the observed plateaus. Furthermore, this argument does not explain which the Hall conductivity is so precisely quantized whereas, a priori, one would expect that being a transport coefficient, the Hall conductivity would depend on lots of complicated material details. But, it turns out that it does not!

Let us first discuss the observed *universality* of the Hall conductivity, namely its robustness and independence of microscopic details. In a remarkable paper, Niu et al. (1985) showed that, provided the ground state is separated by a finite energy gap from the excited states, the Hall conductivity is actually a topological invariant. The argument has a similarity with what we discussed in the case of the Hall effect on a 2D lattice (in Section “The quantum Hall effect on a lattice”) but in this more general system, one considers the full many-body wave function rather than the one-particle states. To show that this is true, they considered a system of N electrons with periodic boundary conditions, that is, on a two-dimensional torus, $T^2 = S_1 \times S_1$, with N_ϕ flux quanta going through the torus. The torus is a rectangle of dimensions L_1 and L_2 with opposite ends identified. This is necessary to allow for a Hall current to be globally allowed. The electromagnetic gauge field for a system on a torus with uniform nonvanishing flux cannot obey periodic boundary conditions but rather across the torus, the gauge fields must differ by (large) gauge transformations

$$A_1(x_1, x_2 + L_2) = A_1(x_1, x_2) + \partial_1 \beta_2(x_1, x_2), \quad A_2(x_1 + L_1, x_2) = A_2(x_1, x_2) + \partial_2 \beta_1(x_1, x_2) \quad (378)$$

while the wave functions themselves obey twisted boundary conditions

$$\begin{aligned} \Psi([\mathbf{x}^{(j)} + L_1 \mathbf{e}_1]) &= \exp\left(-i \frac{e}{\hbar c} \sum_{j=1}^{N_e} \beta_1([\mathbf{x}^{(j)}]) + i\theta_1\right) \times \Psi([\mathbf{x}^{(j)}]) \\ \Psi([\mathbf{x}^{(j)} + L_2 \mathbf{e}_2]) &= \exp\left(-i \frac{e}{\hbar c} \sum_{j=1}^{N_e} \beta_2([\mathbf{x}^{(j)}]) + i\theta_2\right) \times \Psi([\mathbf{x}^{(j)}]) \end{aligned} \quad (379)$$

where $\mathbf{e}_j$ (with $j = 1, 2$) are two unit vectors on the torus, and θ_1 and θ_2 are two angles that *twist* the boundary conditions of the wave functions.

In order to have a current on the torus, they assumed that, in addition to the uniform flux going through the torus, there a weak uniform electric field E on the torus represented by the constant in space vector potential $\delta A = E t = \nabla[U(\mathbf{x})t]$ whose circulation on the two noncontractible circles Γ_1 and Γ_2 , which wrap around the directions x_1 and x_2 of the torus T^2 , are

$$I_j = \oint_{\Gamma_j} \delta A \cdot d\mathbf{x} = t \oint_{\Gamma_j} E \cdot d\mathbf{x} = itE_j L_j. \quad (380)$$

Line integrals of a gauge field on noncontractible loops in space (or space-time) are called *holonomies*. By inspection, we see that the angles θ_1 and θ_2 are given by

$$\theta_j = \frac{e}{\hbar c} I_j \quad (381)$$

Alternatively, the angles $\boldsymbol{\theta} = (\theta_1, \theta_2)$ can be interpreted as magnetic fluxes (in units of the flux quantum ϕ_0) through the two noncontractible circles of the torus T^2 .

The angles $\boldsymbol{\theta}$ are defined as mod 2π since they are phase factors that twist the phase of the wave functions, and define a 2-torus of boundary conditions. By comparing with what we did in Section “The quantum Hall effect on a lattice” in the case of the single-particle wave functions in the lattice model, we see that the *many-body wave function* $\Psi_{\boldsymbol{\theta}}$ and the twist angles $\boldsymbol{\theta}$ are the same as the relation between the phase of the Hofstadter wave functions and the momentum $\mathbf{k}$ of the magnetic BZ (which is also a 2-torus). Indeed, as it is always the case, while the phase of (in this case) the many-body wave function $\Psi_{\boldsymbol{\theta}}$ is arbitrary, the changes of this phase as the twist angle $\boldsymbol{\theta}$ is changed are not. To quantify this dependence, for a given many-body state $\Psi_{\boldsymbol{\theta}}^{(\alpha)}$, where α labels the state, we define a Berry connection $\mathcal{A}^{(\alpha)}(\boldsymbol{\theta})$ on the torus of boundary conditions $\boldsymbol{\theta}$

$$\mathcal{A}^{(\alpha)}(\boldsymbol{\theta}) = i \left\langle \Psi_{\boldsymbol{\theta}}^{(\alpha)} \left| \partial_{\boldsymbol{\theta}} \right| \Psi_{\boldsymbol{\theta}}^{(\alpha)} \right\rangle. \quad (382)$$

Under a redefinition of the phase of the state

$$\Psi_{\boldsymbol{\theta}}^{(\alpha)} \rightarrow \exp(if(\boldsymbol{\theta})) \Psi_{\boldsymbol{\theta}}^{(\alpha)} \quad (383)$$

the Berry connection $\mathcal{A}^{(\alpha)}(\boldsymbol{\theta})$ changes by a gauge transformation

$$\mathcal{A}^{(\alpha)}(\boldsymbol{\theta}) \rightarrow \mathcal{A}^{(\alpha)}(\boldsymbol{\theta}) - \partial_{\boldsymbol{\theta}} f(\boldsymbol{\theta}). \quad (384)$$

Niu et al. (1985) showed that the expression of the Kubo formula for the Hall conductivity of the state $\Psi_{\boldsymbol{\theta}}^{(\alpha)}$, averaged over the boundary conditions $\boldsymbol{\theta}$, is given in terms of the flux of the Berry connection $\mathcal{A}^{(\alpha)}(\boldsymbol{\theta})$ through the 2-torus of boundary conditions, by the gauge-invariant quantity

$$\langle (\sigma_{xy})_{\alpha} \rangle_{\boldsymbol{\theta}} = \frac{e^2}{h} \int_0^{2\pi} \frac{d\theta_1}{2\pi} \int_0^{2\pi} \frac{d\theta_2}{2\pi} \left(\partial_1 \mathcal{A}_2^{(\alpha)} - \partial_2 \mathcal{A}_1^{(\alpha)} \right) = \frac{e^2}{h} \frac{1}{2\pi} \oint_{\gamma} \mathcal{A}^{(\alpha)}(\boldsymbol{\theta}) \cdot d\boldsymbol{\theta} \quad (385)$$

where γ is the square contour with corners at $(0, 0)$, $(2\pi, 0)$, $(0, 2\pi)$, and $(2\pi, 2\pi)$, which defines the 2-torus of boundary conditions $\boldsymbol{\theta}$. This result is known as the Niu–Thouless–Wu formula.

Eq. (385) implies that for the Hall conductivity to be nonvanishing, the Berry connection $\mathcal{A}^{(\alpha)}(\boldsymbol{\theta})$ must have a nonvanishing flux through the torus of boundary conditions. For this to be true, just as we did in Section “Chern invariants,” we must consider large gauge transformations of the form

$$\begin{aligned} \mathcal{A}_1(\boldsymbol{\theta} + 2\pi \mathbf{e}_2) &= \mathcal{A}_1(\boldsymbol{\theta}) + \partial_1 f_2(\boldsymbol{\theta}) \\ \mathcal{A}_2(\boldsymbol{\theta} + 2\pi \mathbf{e}_1) &= \mathcal{A}_2(\boldsymbol{\theta}) + \partial_2 f_1(\boldsymbol{\theta}) \\ \Psi^{(\alpha)}(\{\mathbf{x}^{(j)}\}; \boldsymbol{\theta} + 2\pi \mathbf{e}_1) &= \exp(if_1(\boldsymbol{\theta})) \Psi^{(\alpha)}(\{\mathbf{x}^{(j)}\}; \boldsymbol{\theta}) \\ \Psi^{(\alpha)}(\{\mathbf{x}^{(j)}\}; \boldsymbol{\theta} + 2\pi \mathbf{e}_2) &= \exp(if_2(\boldsymbol{\theta})) \Psi^{(\alpha)}(\{\mathbf{x}^{(j)}\}; \boldsymbol{\theta}) \end{aligned} \quad (386)$$

where $\mathbf{e}_1$ and $\mathbf{e}_2$ are two orthogonal unit vectors on the torus of boundary conditions. We can now repeat the analysis we did in Section “Chern invariants” which, in this context, implies that the wave function $\Psi_{\boldsymbol{\theta}}^{(\alpha)}$ cannot be globally well defined on the torus of boundary conditions, where it must have zeros, and where it should be defined in patches. The end result is that the wave functions labeled by α are classified by a *topological invariant*, the first-valued Chern number $C_1^{(\alpha)}$, which is given here by

$$C_1^{(\alpha)} = \frac{1}{2\pi} \oint_{\gamma} \mathcal{A}^{(\alpha)}(\boldsymbol{\theta}) \cdot d\boldsymbol{\theta} \quad (387)$$

and, hence, that the Hall conductivity in the state α (averaged over the twisted boundary conditions) exhibits the integer quantum Hall effect,

$$\langle (\sigma_{xy})^{(\alpha)} \rangle_{\boldsymbol{\theta}} = C_1 \frac{e^2}{h}. \quad (388)$$

Expressing the Hall conductivity in terms of the first Chern number, which is a topological invariant, proves that the value of the conductivity cannot be changed by local physics effects, such as disorder. The topological nature of the Hall conductivity is the reason for the robustness and high precision of the measured value of the Hall conductivity. In subsequent work Niu and Thouless showed that, provided the state has a finite energy gap to all excitations, in the thermodynamic limit the Hall conductivity averaged over boundary conditions and for a given boundary condition are equal.

The result of Eq. (388) seemingly implies that there can only be an *integer* quantum Hall effect which, as we see shortly, is not the case: there is a fractional quantum Hall effect in which the Hall conductivity is a *fraction*, $\sigma_{xy} = \frac{p}{q} \frac{e^2}{h}$, where p and q are co-prime integers. This value of the Hall conductivity is also found experimentally to be obeyed with the same precision as in the integer quantum Hall effect. In other words, the Hall conductivity in the fractional case must also have a topological character. To understand why this can be the case, we need an implicit assumption that we made in our derivation. In fact, in deriving the result of Eq. (388), we assumed (implicitly) that for each value of $\boldsymbol{\theta}$ there is only one many body state $\Psi_{\boldsymbol{\theta}}^{(\alpha)}$ (up to gauge transformations). As we will see below, in the *fractional* quantum Hall effect on a torus (and, in fact on any closed surface except the sphere), the ground state is degenerate in the thermodynamic limit. We will also see that traversing the torus of boundary conditions once maps one degenerate state to another one. In general, we will find that on the 2-torus in the thermodynamic limit, there are $m \in \mathbb{Z}$ exactly degenerate states. In this case, one returns to the original state after sweeping m times the torus of boundary conditions. We will also see below that the degenerate states are labeled by quantum numbers related to the *anyons* that they support.

While the topological argument proves the robustness (and universality) of the value of the Hall conductivity, it does not provide an insight for why there are plateaus in its magnetic field dependence. If for some value of the filling fraction $\nu = N/N_{\phi}$, the electron fluid is exactly at a ground state $\Psi^{(\alpha)}$ upon changing either the number of particles N or the magnetic field B (but not both), the fluid will now be at the state $\Psi^{(\alpha)}$ plus or minus some number of electrons. The existence of the plateau in σ_{xy} can be understood if the extra electrons (or holes) do not contribute to the Hall conductivity. This happens in the presence of disorder as these extra particles will be localized by the disorder and localized states, whose wave functions decay exponentially are insensitive to boundary conditions and, hence, these states do not contribute to the conductivity. This argument was first put forth by Laughlin (1981) who built on the result that in a disordered system in two dimensions, all states are localized (Abrahams et al., 1979) but made the key assumption that the state at the center of the Landau level (broadened by disorder) is extended and contributes to the conductivity if this state is filled. This picture implies that this is actually a quantum phase transition from an insulator (dubbed a Hall insulator) to a state with a quantized Hall conductivity.

This intuitive and appealing proposal has been the focus of research for many years and it is largely an unsolved problem. There is in fact a proposed field theory for this quantum phase transition based on a nonlinear sigma model (in replica space) with a topological θ term (Levine et al., 1983; Pruisken, 1984), analogous to the theory we discussed in Section “Nonlinear sigma models and antiferromagnetic quantum spin chains” for quantum antiferromagnets in 1+1 dimensions. In this proposal, the (Boltzmann) longitudinal conductivity σ_{xx} plays the role of the inverse of the coupling constant of the nonlinear sigma model while σ_{xy} plays the role of the coefficient of the θ term. Although the RG flows suggested by this approach qualitatively agree with currently existing experimental data, actual derivation is still wanting.

However, aside from the fact that it is still an unsolved problem, there is the problem that this explanation ignores the fact that in a Landau level interactions are dominant and are the key to the understanding of the fractional case even in the same samples! A symptom of this problem is that, at least in the cleaner samples, as we noted above, the longitudinal conductivity vanishes exponentially with temperature. This dependence means that there is a clean energy gap (and not just a mobility gap), which suggests that the state with additional excitations may have some sort of at least local order, which would provide for a local energy gap. An actual theory based on this picture has yet to be developed.

The Laughlin wave function

We will turn now to the *fractional* quantum Hall effect (FQHE). The FQHE is observed in fractionally filled Landau levels. These states have fractional filling fractions, namely that $\nu = \frac{N_e}{N_\phi}$ is a fraction. Most of the observed states are in the lowest Landau level, with $N = 0$, but a few states with very intriguing properties are seen in the first excited Landau Level with $N = 1$.

Let us consider for now the states in the lowest Landau level, $N = 0$. We will assume that there is no disorder and, for now, we will ignore the effects of boundaries of the sample. Physically, the important interaction here is the Coulomb interaction although, in some samples with screening layers, short-range interactions may be important as well. Since there is a large magnetic field, the Zeeman interaction is typically a large energy scale and the electrons are expected to be fully polarized. However, there are situations under which the gyromagnetic factor can be made small (and even zero) and spin unpolarized states have to be considered. In some platforms, such as graphene, additional quantum numbers are present, such as “flavor” associated with the different Dirac states. In our discussion we will not cover these richer possibilities.

Under these circumstances, we have a problem in which all N_ϕ available one-particle states are exactly degenerate (the Landau level is “flat”) but only a fraction of them are filled. In this limit, this system as strongly interaction as it gets. Not surprisingly, in a system of this type, time-honored standard approximations fail, such as Hartree–Fock. Given the macroscopic degeneracy and the nature of the states in a magnetic field, a system of this type may harbor many different types of actual ground states depending of the types of interactions that are considered.

Tsui et al. (1982) did transport experiments in the two-dimensional electron gas (2DEG) in high-purity GaAs–AlAs heterostructures and reported the discovery of a state with a highly precise value of the Hall conductivity of $\sigma_{xy} = \frac{1}{3} \frac{e^2}{h}$. Such a state cannot be understood in any obvious way in terms of the integer quantum Hall effect. The observation of a clean gap in the low temperature longitudinal resistivity $\sigma_{xx} \rightarrow 0$ as $T \rightarrow 0$ implied that the 2DEG is incompressible and quite likely uniform.

The first breakthrough was Laughlin’s unique insight, which led to his explanation of the experiments in terms of a novel quantum liquid of fully spin-polarized electrons at filling fractions $\nu = \frac{1}{m}$ (with m and odd integer) whose wave function he proposed to be

$$\Psi_m(z_1, \dots, z_N) = \prod_{i < j} (z_i - z_j)^m \times \exp \left(- \sum_{i=1}^{N_e} \frac{|z_i|^2}{4\ell_0^2} \right) \quad (389)$$

where $N = N_e$ is the number of electrons, $\{z_i\}$ are their (complex) coordinates, and m is an odd integer (which makes the wave function antisymmetric, as required by Fermi statistics).

Laughlin extracted the physics encoded in this wave function by considering the probability $|\Psi_m(z_1, \dots, z_N)|^2$ of finding the N electrons in the locations $\{z_i\}$ (with $i = 1, \dots, N$). The norm of the Laughlin wave function is

$$\|\Psi_m\|^2 = \int d^2z_1 \dots d^2z_N |\Psi_m(z_1, \dots, z_N)|^2. \quad (390)$$

The Laughlin wave function $\Psi_m(z_1, \dots, z_N)$ is an eigenstate of angular momentum with eigenvalue $L_m = \frac{1}{2}mN(N-1)$. This remarkable wave function has a large overlap ($\sim 98\%$) with the exact wave function with $V(R) = \frac{e^2}{\epsilon R}$ (Coulomb) interactions in systems of up to eight particles (ϵ is the dielectric constant).

The norm of the state can then be interpreted as the classical partition function of a system of a system of N particles at the locations $\{z_i\}$ at inverse temperature $\beta = m$ with the effective interaction

$$U(z_1, \dots, z_N) = -2 \sum_{1 \leq i < j \leq N} \ln |z_i - z_j| + \frac{1}{2m\ell_0^2} \sum_{j=1}^N |z_j|^2. \quad (391)$$

This classical partition function is a one-component plasma, of a gas of particles with unit (negative) charge interacting with each other with the repulsive 2D classical (logarithmic!) Coulomb interaction, $V_{CG} = -\ln |z_i - z_j|$ (not $1/R!$). The last term represents the contribution of a neutralizing background positive charge (which here it originates in the Gaussian factor of the wave function).

In other words, this is a one-component plasma. We can check that this is correct since $\nabla^2 \left(\frac{|z|^2}{2m\ell_0^2} \right) = \frac{2}{m\ell_0^2}$, which corresponds to a uniform (areal) charge density $\rho_0 = \frac{1}{2\pi m\ell_0^2}$. Classical Monte Carlo simulations of this probability distribution showed that this wave function describes an incompressible fluid state if $m \leq 7$ while for larger values, it represents a crystalline state. This approach is known as the plasma analogy.

Quasiholes have fractional charge

Laughlin considered a vortex-like excitation in the fluid created by the adiabatic insertion of an infinitesimally thin solenoid at some coordinate z_0 carrying a magnetic flux Φ , a *fluxoid*. In the presence of this solenoid, the single particle state $z^n \exp(|z|^2/4\ell_0^2)$ acquires a branch cut and becomes the state $z^{n+\alpha} \exp(|z|^2/4\ell_0^2)$ where $\alpha = \Phi/\phi_0$, with $\phi_0 = hc/e$ being the flux quantum. This analytic structure is the Aharonov–Bohm effect (Aharonov and Bohm, 1959).

However, if the solenoid carries just one flux quantum $\alpha = 1$ and the net effect is that the state becomes $z^{n+1} \exp(-|z|^2/4\ell_0^2)$ which has one more unit of angular momentum. For these reasons, in the presence of a solenoid with one flux quantum inserted at z_0 , the Laughlin wave function for the 2DEG in a large magnetic field now becomes

$$\Psi_m^{qh}(z_0; z_1, \dots, z_N) = \prod_{i=1}^N (z_i - z_0) \times \Psi_m(z_1, \dots, z_N). \quad (392)$$

A calculation using the plasma analogy reveals that the net effect of the solenoid is to expel a charge equal to $-e/m$ from the vicinity of the location of the solenoid or, equivalently, to create a *fractionally charged quasihole* at z_0 with charge $Q_{qh} = +e/m$. The charge distribution is uniform at long distances but is depleted (hence a quasihole) on a length scale ξ . One can check that this state costs a finite energy ε_0 , which depends on the particular interaction.

On the other hand, if we consider a system in which the solenoid is inserted adiabatically so that after a long time t there is a quasihole at z_0 , an amount of charge equal to $-e/m$ will flow radially outwards to the outer edge of the 2DEG. The adiabatic insertion of the solenoid generates an azimuthal electric field (an e.m.f.) and a radial Hall current, and a Hall conductivity $\sigma_{xy} = \frac{1}{m} \frac{e^2}{h}$. Hence, the Laughlin wave function exhibits the fractional quantum Hall effect and its excitations are vortices with fractional charge e/m .

It is important to note the nonlocal nature of the Laughlin quasihole. The nonlocality is inherited from the fluxoid (the solenoid) inserted at z_0 : even though the magnetic field of the fluxoid vanishes away from it, $B(\mathbf{x}) = \Phi \delta^2(\mathbf{x} - \mathbf{x}_0)$, its vector potential $A(\mathbf{x})$ does not since its circulation on any noncontractible loop γ that contains the location of the fluxoid inside must be equal to the flux Φ carried by the fluxoid. Although in principle one can choose a singular gauge in which $A(\mathbf{x})$ vanishes locally, this cannot be true everywhere as it must leave behind a Dirac-like string on a curve Γ ranging from the location z_0 of the fluxoid to the boundary of the system with A taking a singular value on Γ . This feature has the same form as the 2D vortex that we discussed in Section “Vortices in two dimensions.” Kivelson and Rokhsar (1985) showed that the existence of this Dirac string causes the *phase* of a quantum state that carries charge e^* to have a branch cut on the curve Γ and to change by $\exp(i2\pi(e^*/e)\Phi/\phi_0)$, as required by the Aharonov–Bohm effect (Aharonov and Bohm, 1959). This effect is unobservable for integer-charged states, that is, electrons.

The Jain states

The construction of the Laughlin quasihole motivated Jain (1989a,b) to rewrite the Laughlin wave function in the form

$$\Psi_m(z_1, \dots, z_N) = \prod_{i < j} (z_i - z_j)^{m-1} \times \Psi_{v=1}(z_1, \dots, z_N). \quad (393)$$

Here the prefactor represents particles each attached with an even number, $m-1$, of flux quanta. The second factor, $\Psi_{v=1}(z_1, \dots, z_N)$, is the wave function of fermions filling up a lowest Landau level, that is, the Vandermonde determinant of Eq. (377). In this form, the inverse of the filling factor, $1/\nu$, which is the number of flux quanta per particle, is written as $\frac{1}{\nu} = (m-1) + 1 = m$. The interpretation now is that the $(m-1)\phi_0$ magnetic flux carried by each particle, which partially screens the uniform field down to an effective field $B_{\text{eff}} = B - (m-1)\phi_0$ corresponding to one effective flux quantum per particle, that is, a filled lowest Landau level of the effective field B_{eff} . In other words, the wave function for the $\nu = 1/m$ FQH state is reinterpreted as the $\nu_{\text{eff}} = 1$ integer QH state of N composite fermions, each being an electron carrying attached an even integer $m-1$ flux quanta.

This procedure is known as flux attachment. Physically it means that the strong interactions between the electrons for other electrons to be further away which, in virtue of being in a strong magnetic field, is equivalent to an increase of their relative angular momentum, as if there was a local change in the magnetic field. There is no reason to believe that the composite fermions are weakly coupled, even though this is frequently stated in the literature without any real supporting evidence.

Jain then generalized this reinterpretation of the Laughlin state to a whole sequence of FQH states obtained by filling p levels of these partially screened magnetic fluxes

$$\Psi_{m,p}(z_1, \dots, z_N) = P_{LL} \prod_{i < j} (z_i - z_j)^{m-1} \Psi_{v=p}(z_1, \dots, z_N) \quad (394)$$

where $\Psi_{v=p}(z_1, \dots, z_N)$ is the wave function of p -filled Landau levels (of composite fermions), and P_{LL} is an operator that projects onto the lowest Landau level. By counting fluxes, we see that the filling fractions for the Jain states satisfy

$$\frac{1}{v(m, p)} = m - 1 \pm \frac{1}{p} \quad (395)$$

where we allowed for the possibility that the external fluxes may be over-screened by the composite fermions. Alternatively we can write

$$v(m, p) = \frac{p}{p(m-1) \pm 1}. \quad (396)$$

The Jain states with $p = 1$ are the Laughlin states and each is called the primary state of a Jain sequence. Almost all the observed FQH states belong to one of these sequences (and its generalizations). In particular, the most prominent states (i.e., those with larger plateaus) belong to the sequence $\frac{1}{3}, \frac{2}{5}, \frac{3}{7}, \frac{4}{9}, \frac{5}{11}, \dots$ and to the reversed sequence $1, \frac{2}{3}, \frac{3}{5}, \frac{4}{7}, \dots$. For $p \rightarrow \infty$, the Jain sequences converge to the values of the filling fraction $\lim_{p \rightarrow \infty} v(m, p) = \frac{1}{m-1}$. In this limit, the $m-1$ fluxes attached to each particle exactly cancels the external flux leading us to a (possibly) FL of composite fermions (Halperin et al., 1993).

Quasiholes have fractional statistics

The nonlocality and topological nature of the Laughlin quasihole imply that this state must be regarded as a soliton (or vortex) of the charged quantum fluid. The vortex-like state with wave function $\Psi_m^{qh}(z_0; z_1, \dots, z_N)$ is called the Laughlin quasihole. This state represents a composite object of a flux quantum and a fractional charge. This structure of this quantum state is strongly reminiscent of the flux-charge composite objects considered by Frank Wilczek who showed that such objects should be *anyons*, states that exhibit *fractional statistics* (Wilczek, 1982a). Although at a conceptual level anyons were proposed (almost) prior to the discovery of the FQHE, it is in this setting that fractional statistics entered actual physics. The actual experimental observation took work by many people, and was only confirmed in 2020 (Nakamura et al., 2020).

Fractional statistics dictates the analytic form of the wave functions of two or more quasiholes (Halperin, 1984). Let us consider a Laughlin-type wave function for two quasiholes located at (complex) coordinates u and w . Naively we expect the wave function for two quasiholes in the $v = 1/m$ Laughlin state to have the form

$$\Psi(u, w; z_1, \dots, z_N) = N(u, w) \prod_{j=1}^N (z_j - u)(z_j - w) \Psi_m(z_1, \dots, z_N) \quad (397)$$

The prefactor $N(u, w)$ must be chosen to account for the fact that there is an additional change of angular momentum due to the additional fluxoid at w . We also expect that as the quasihole with charge e/m is adiabatically carried around the other quasihole (also with charge e/m), there will be an accrued phase in the wave function due to the Aharonov-Bohm effect of the charge of one quasihole circling around the flux of the other (or, equivalently, crossing the branch cut) (Kivelson and Rok, 1985). The requirement of translation invariance and analyticity is met by the choice (Halperin, 1984) (ignoring a multiplicative normalization constant)

$$N(u, w) = (u - w)^{1/m} \exp\left(-\frac{1}{4\ell_0^2 m}(|u|^2 + |w|^2)\right) \quad (398)$$

which has a branch cut stretching from u to w . A calculation using the plasma analogy represents this state as a set of N charge -1 particles interacting with two additional particles of charge $-1/m$ at u and w (and a neutralizing background). The branch cut implies that dragging a quasihole around the other during a π rotation followed by a translation (i.e., an exchange) induces a monodromy in the wave with a jump in its phase of $\exp(\pm i\pi/m)$ (with the sign determined by the orientation of the monodromy) in such a way that the wave function changes by a phase factor

$$\Psi(u, w; z_1, \dots, z_N) \mapsto e^{\pm i\frac{\pi}{m}} \Psi(u, w; z_1, \dots, z_N). \quad (399)$$

In other words, the quasihole is an *anyon* with fractional statistics π/m . Arovas et al. (1984) further refined this argument by showing that under such a slow adiabatic change the wave function of two quasiholes acquires a Berry phase, which accounts for the fractional statistics. An explicit path-integral derivation of this effect, which uses the fact that the quasihole states are coherent states can be found in Fradkin (2013), Chapter 13.

Hydrodynamic effective field theory

We will now turn to the approaches to the FQHE using the methods of quantum field theory. As we will see, the concept of flux attachment plays a key role. In Section “Quantization of Abelian Chern–Simons gauge theory,” we showed that Chern–Simons gauge theory is in fact a theory of flux attachment. Thus we expect that Chern–Simons gauge theory should play a key role as well.

It is useful to ask first why should Chern–Simons gauge theory play a central role at least in the description of the low energy physics. There is a simple, yet powerful, phenomenological argument due to Jörg Fröhlich and Anthony Zee that shows why this should be the case (Fröhlich and Zee, 1991). This is essence a hydrodynamic argument. The fractional quantum Hall effect occurs in a 2DEG in the presence of a large magnetic field which breaks explicitly time-reversal invariance. In the regime of the FQHE, the 2DEG is a uniform charged incompressible fluid in which charge is conserved. This means that the charge 3-current $j_\mu = (j_0, \mathbf{j})$ (where j_0 is the charge density and $\mathbf{j}$ is the charge current density) must be locally conserved,

$$\partial_\mu j^\mu = 0 \quad (400)$$

which is the continuity equation. The solution of this equation is that the conserved current can be written in terms of a *dual* (in the Hodge sense) vector field $\mathcal{B}_\mu$ such that

$$j_\mu = \frac{1}{2\pi} \epsilon_{\mu\nu\lambda} \partial^\nu \mathcal{B}^\lambda. \quad (401)$$

The factor of $\frac{1}{2\pi}$ is introduced for later convenience. The current field j_μ is not changed by a smooth redefinition of the vector field $\mathcal{B}_\mu \rightarrow \mathcal{B}_\mu + \partial_\mu \Phi$, where $\Phi(x)$ is a nonsingular field. This means that the vector field $\mathcal{B}_\mu$ is a gauge field.

The effective action of this theory is a functional of the current distribution j_μ and, hence, of the gauge field $\mathcal{B}_\mu$. It should be gauge-invariant, and odd under parity and time reversal. Since the fluid is incompressible and uniform, at long distances and low energies the action must be a local functional of the gauge field which should be at least Galilean invariant. In addition, the coupling of the fluid to an external electromagnetic probe field A_μ must be of the usual form $-ej^\mu A_\mu$. To lowest orders in derivatives, there the unique local and gauge-invariant Lagrangian density which is odd under time reversal (and parity) is the Chern–Simons theory

$$\mathcal{L}_{\text{eff}}[\mathcal{B}_\mu] = \frac{m}{4\pi} \epsilon_{\mu\nu\lambda} \mathcal{B}^\mu \partial^\nu \mathcal{B}^\lambda - \frac{1}{4g^2} \mathcal{F}_{\mu\nu}^2 - \frac{e}{2\pi} A^\mu \epsilon_{\mu\nu\lambda} \partial^\nu \mathcal{B}^\lambda + \dots \quad (402)$$

The first term is the Chern–Simons term of the Lagrangian. The coefficient m is a dimensionless integer which, as we saw in Section “Chern–Simons gauge theory” is required for the theory to be invariant on a closed manifold. The second is a Maxwell term. Here $\mathcal{F}_{\mu\nu} = \partial_\mu \mathcal{B}_\nu - \partial_\nu \mathcal{B}_\mu$ is the field strength tensor of the gauge field $\mathcal{B}_\mu$. By power counting, we see that the coupling constant g^2 has units of length^{-1} and, hence this term is irrelevant at long distances and will be neglected. The third term is the coupling of the current j_μ to the electromagnetic field A_μ . Upon an integration by parts this term can be written as $\mathcal{B}_\mu \mathcal{J}^\mu$ where

$$\mathcal{J}_\mu = -\frac{e}{2\pi} \epsilon_{\mu\nu\lambda} \partial^\nu A^\lambda \quad (403)$$

is a current minimally coupled to $\mathcal{B}_\mu$.

The equation of motion of the (dynamical) gauge field $\mathcal{B}_\mu$ is

$$\frac{\delta \mathcal{L}}{\delta \mathcal{B}} = 0 \quad (404)$$

which yields the relation

$$\frac{m}{2\pi} \epsilon_{\mu\nu\lambda} \mathcal{B}^\mu \partial^\nu \mathcal{B}^\lambda = \mathcal{J}_\mu \quad (405)$$

From the definition of the current $\mathcal{J}_\mu$, Eq. (403), we see that the solution of the equation of motion of Eq. (405), up to a gauge transformation, is

$$m\mathcal{B}_\mu = -eA_\mu. \quad (406)$$

By plugging this relation back into the Lagrangian for the gauge field $\mathcal{B}_\mu$, Eq (402) (which is equivalent to integrate out the gauge field $\mathcal{B}_\mu$) we find that the effective Lagrangian of the electromagnetic field A_μ is just a Chern–Simons term

$$\mathcal{L}_{\text{eff}}[A_\mu] = \frac{e^2}{4\pi m} \epsilon_{\mu\nu\lambda} A^\mu \partial^\nu A^\lambda + \dots \quad (407)$$

This result allows us to read-off the Hall conductivity of the fluid

$$\sigma_{xy} = \frac{1}{m} \frac{e^2}{2\pi\hbar} \quad (408)$$

where we restored units such that $\hbar$ is not unity. In other words, this fluid exhibits the fractional quantum Hall effect for a fluid at filling fraction $\nu = 1/m$.

We should note that this heuristic argument applies equally to systems of fermions, for which m is odd, as well as to systems of bosons, for which m is even.

Composite Boson field theory

We will now discuss two field-theoretic approaches to the FQHE. These approaches use the concept of flux attachment as a mapping of fermions to bosons and as a mapping of fermions to fermions. These approaches are a form of duality transformation that engineers a form of statistical transmutation. We will first show that Chern–Simons theory can be used to effect such a mapping. That this is possible should not be surprising since, as we saw in Section “Fractional statistics and braids,” Chern–Simons theory is a theory of fractional statistics and, hence, of anyons.

We should make some important comments on both approaches before we get into a detailed description. While the mapping of fermions to composite bosons and fermions to composite bosons is correct, their approximate mean field descriptions violate symmetries of the 2DEG in a magnetic field. At the root level is the fact that the flux attachment is local in space time and approximate descriptions of these theories bring about a large amount of Landau level mixing, even in the large field limit.

For instance, at the mean field theory level, the composite boson approach is equivalent to a Bose-Einstein condensate which is invariant under translations and under time reversal. In this picture the breaking of time reversal is present in the coupling to a Chern–Simons gauge field. Likewise, the mean field theory of the composite fermion theory is a problem of composite fermions in a partially screened magnetic field. While a partially screened magnetic field still breaks time reversal, it does not behave properly under magnetic translations. As we will see, these problems will be solved, at least in the low-energy regime, by quantum fluctuations which restore the symmetries. In both cases, in the fractional states, one recovers an effective topological field theory, which captures the universal physics of these states. Needless to say it, both approaches do poorly in the computation of nonuniversal dimensionful quantities such as energy gaps. These difficulties become very severe in the compressible states whose low energy behavior is not topological.

Unlike the wave function approaches, which project these states into a specific Landau level (usually the lowest), the field theoretic approach does not effect such projection. Several papers have been written attempting to do a field theory projected into a Landau level. These approaches transformed the problem into quantum field theory on a noncommutative plane, which is inherent in the nature of the states in a magnetic field. Although some significant progress has been made in this direction, these theories remain poorly understood (Pasquier and Haldane, 1998; Read, 1998; Susskind, 2001; Polychronakos, 2001; Fradkin et al., 2002; Dong and Senthil, 2020; Goldman and Senthil, 2022).

In this section, we will focus on the composite boson theory. Let us consider a theory in 2+1 dimensions with two dynamical Abelian gauge fields $\mathcal{A}_\mu$ and $\mathcal{B}_\mu$, whose Lagrangian is a sum of a Chern–Simons term at level k and a BF term:

$$\mathcal{L} = \frac{k}{4\pi} \epsilon_{\mu\nu\lambda} \mathcal{A}^\mu \partial^\nu \mathcal{A}^\lambda + \frac{1}{2\pi} \epsilon_{\mu\nu\lambda} \mathcal{A}^\mu \partial^\nu \mathcal{B}^\lambda \quad (409)$$

The equation of motion for the field $\mathcal{A}_\mu$ is

$$\frac{k}{2\pi} \epsilon_{\mu\nu\lambda} \partial^\nu \mathcal{A}^\lambda + \frac{1}{2\pi} \epsilon_{\mu\nu\lambda} \partial^\nu \mathcal{B}^\lambda = 0 \quad (410)$$

whose solution (up to a gauge transformation) is $k\mathcal{A}_\mu = -\mathcal{B}_\mu$. Plugging this relation into the Lagrangian of Eq. (409) we find that the effective Lagrangian for the field $\mathcal{B}_\mu$ is

$$\mathcal{L}[\mathcal{B}_\mu] = -\frac{1}{4\pi k} \epsilon_{\mu\nu\lambda} \mathcal{B}^\mu \partial^\nu \mathcal{B}^\lambda \quad (411)$$

which states that exchanging $\mathcal{A}_\mu \leftrightarrow \mathcal{B}_\mu$ is equivalent to the “duality” $k \leftrightarrow -1/k$.

In Section “Fractional statistics and braids,” we showed that particles coupled to a Chern Simons gauge field at level k have fractional statistics $\exp(\pm i\pi/k)$. Hence, we see that particles coupled to the field $\mathcal{B}_\mu$ have fractional statistics $\exp(\pm i\pi k)$. In other words, for k odd, this coupling amounts to exchanging a theory of fermions to a theory of bosons coupled to the gauge field $\mathcal{B}_\mu$. This is a form of bosonization. Alternatively, for k even it maps a theory of fermions to another theory of fermions coupled to a gauge field $\mathcal{B}_\mu$. These observations have led to distinct, but ultimately equivalent description of the quantum Hall effect.

We will begin the approach of mapping fermions to bosons and use it in the problem of the FQHE. This is the Landau–Ginzburg theory (or *composite boson theory*) of Zhang et al. (1989) (ZHK). In this approach, the problem of fermions coupled to a magnetic field interacting with each other through a two-body potential (that we will assume is ultra with coupling constant λ , for simplicity) becomes the same problem but for a theory of bosons which are also coupled to a Chern–Simons gauge field, which we will denote by $\mathcal{A}_\mu$. The Lagrangian density for this equivalent system of *composite bosons* is

$$\mathcal{L}_{CB} = \phi^*(x) [iD_0 + \mu] \phi(x) + \frac{1}{2M} |D\phi(x)|^2 - \lambda |\phi(x)|^4 + \frac{1}{4\pi m} \epsilon_{\mu\nu\lambda} \mathcal{A}^\mu \partial^\nu \mathcal{A}^\lambda \quad (412)$$

where $x = (x_0, \mathbf{x})$ are the space-time coordinates, μ is the chemical potential, M is the mass of the fermions, and m is an arbitrary odd integer. The covariant derivative

$$D_\mu = \partial_\mu + i \frac{e}{\hbar c} A_\mu + i \mathcal{A}_\mu \quad (413)$$

which effects the minimal coupling of the complex scalar field $\phi(x)$ to the background electromagnetic field A_μ and to the Chern–Simons gauge field $\mathcal{A}_\mu$, known in this context as known as the statistical gauge field.

ZHK showed that the FQH state can be thought as being closely related to a phase in which the complex scalar field condenses, much as in the case of a superfluid even though the FQH is *not* a superfluid. To see how this works, we will write

$$\phi(x) = \sqrt{\rho(x)} \exp(i\omega(x)). \quad (414)$$

The classical equations of motion of the theory of composite bosons, Eq. (412), are

$$\frac{\delta \mathcal{L}_{CB}}{\delta \phi^*(x)} = 0 \Rightarrow (iD_0 + \mu)\phi(x) - \frac{1}{2M} D^2 \phi(x) - 2\lambda |\phi(x)|^2 \phi(x) = 0 \quad (415)$$

$$\frac{\mathcal{L}_{CB}}{\delta \mathcal{A}_0(x)} = 0 \Rightarrow \frac{1}{2\pi m} \epsilon_{ij} \partial_i \mathcal{A}_j + |\phi(x)|^2 = 0 \quad (416)$$

$$\frac{\mathcal{L}_{CB}}{\delta \mathcal{A}_i(x)} = 0 \Rightarrow \frac{1}{2\pi m} \epsilon_{i\alpha\beta} \partial^\alpha \mathcal{A}^\beta + \frac{i}{2M} [\phi^*(x) D_i \phi(x) - (D_i \phi(x))^* \phi(x)] = 0 \quad (417)$$

$$\frac{\mathcal{L}_{CB}}{\delta \mu} = \rho_0 L^2 T \Rightarrow \int d^3x |\phi(x)|^2 = \rho_0 L^2 T \quad (418)$$

where ρ_0 is the areal density of electrons.

A uniform solution of Eqs. (415)–(418) with constant amplitude of the composite bosons, that is, a uniform and static condensate $\bar{\phi}$, with uniform statistical gauge field strength $\bar{\mathcal{B}}$, requires that there should be no current in the ground state and that each term of Eq. (417) should be zero. This condition implies that the external field is canceled by the average statistical field, $\frac{eB}{\hbar c} + \bar{\mathcal{B}} = 0$. This condition together with Eqs. (416) and (418) implies that

$$\rho_0 = \frac{1}{m} \frac{eB}{\hbar c} = \frac{1}{2\pi\ell_0^2} \quad (419)$$

and we conclude that the filling fraction is $\nu = \frac{1}{m}$ which are the Laughlin states. In addition we get that the chemical potential is $\mu = 2\lambda\rho_0$ and that $|\bar{\phi}|^2 = \rho_0$, with ρ_0 given in Eq. (419).

However, these mean field results seem to imply that this system is a Bose-Einstein condensate. To understand why this is incorrect, and to determine what it actually is, we need to go beyond the mean field theory that we just described and evaluate the effects of quantum fluctuations and write

$$\phi(x) = (\rho_0 + \delta\rho(x))^{1/2} \exp(i\omega(x)), \quad \frac{eA_\mu}{\hbar c} + \mathcal{A}_\mu = \delta\mathcal{A}_\mu. \quad (420)$$

The partition function of this theory is a path integral over the fluctuating density fields $\delta\rho$, the Goldstone field ω , and the fluctuation of the Chern–Simons gauge field $\delta\mathcal{A}_\mu$. Upon integrating out the massive density fluctuations to lowest (quadratic) order, we find that the effective Lagrangian for ω and $\delta\mathcal{A}_\mu$ is

$$\mathcal{L}_{\text{eff}}[\omega, \delta\mathcal{A}_\mu] = \frac{\kappa}{2} (\partial_0\omega - \delta\mathcal{A}_0)^2 - \frac{\rho_s}{2} (\partial_i\omega - \delta\mathcal{A}_i)^2 + \frac{1}{4\pi m} \epsilon_{\mu\nu\lambda} \delta\mathcal{A}^\mu \partial^\nu \delta\mathcal{A}^\lambda + \dots \quad (421)$$

The first two terms of Eq. (421) is the effective Lagrangian of the Goldstone mode ω in the Bogoliubov theory of superfluidity a compressibility κ and a superfluid stiffness ρ_s given by

$$\kappa = \frac{1}{2\lambda}, \quad \rho_s = \frac{\rho_0}{M} = \frac{\nu}{2\pi} \hbar\omega_c. \quad (422)$$

However, as we see, this is not a superfluid since the phase field is “eaten” by the Chern–Simons gauge field $\delta\mathcal{A}_\mu$, which now acquires a mass term. In this sort of Higgs mechanism, the fluctuating gauge field has a massive longitudinal mode and a massive transverse mode. Thus, this state does not have any massless modes.

To see that this theory describes the fractional quantum Hall effect, we need to compute the linear response to a weak electromagnetic perturbation $\delta A_\mu(x)$. This can be accomplished by considering the new Lagrangian

$$\mathcal{L}_{\text{eff}}[\omega, \delta\mathcal{A}_\mu, \delta A_\mu] = \frac{\kappa}{2} \left(\partial_0\omega - \delta\mathcal{A}_0 - \frac{e}{\hbar c} \delta A_0 \right)^2 - \frac{\rho_s}{2} \left(\partial_i\omega - \delta\mathcal{A}_i - \frac{e}{\hbar c} \delta A_i \right)^2 + \frac{1}{4\pi m} \epsilon_{\mu\nu\lambda} \delta\mathcal{A}^\mu \partial^\nu \delta\mathcal{A}^\lambda + \dots \quad (423)$$

and integrate the phase field ω (which can be set to zero in the London/unitary gauge) and the fluctuation of the statistical field $\delta\mathcal{A}_\mu$ to find that effective electromagnetic action is

$$S_{\text{eff}}[\delta A_\mu] = \frac{1}{4\pi m} \frac{e^2}{\hbar} \int d^3x \epsilon_{\mu\nu\lambda} \delta A^\mu \partial^\nu \delta A^\lambda + \dots \quad (424)$$

from which we conclude that the Hall conductivity predicted by the composite boson theory is

$$\sigma_{xy} = \frac{1}{m} \frac{e^2}{\hbar} \quad (425)$$

as it should be for a FQHE at filling fraction $\nu = 1/m$.

We conclude by looking at vortex states in the composite boson theory. A vortex state is a time-independent solution of the equations of motion Eqs. (415)–(418) with the asymptotic behavior (in the temporal gauge $\delta\mathcal{A}_0 = 0$)

$$\lim_{|x| \rightarrow \infty} \phi(x) = \sqrt{\rho_0} e^{i\varphi(x)} \quad (426)$$

$$\lim_{|x| \rightarrow \infty} \delta\mathcal{A}_i(x) = \pm \partial_i \varphi(x) = \pm \epsilon_{ij} \frac{x_j}{|x|^2} \quad (427)$$

where $\varphi(x)$ is the azimuthal angle on the plane

$$\varphi(x) = \tan^{-1} \left(\frac{x_2}{x_1} \right). \quad (428)$$

The energy of a neutral vortex (i.e., not coupled to a gauge field) is logarithmically divergent, $E_{\text{vortex}} \simeq \frac{\rho_s}{2} \ln(R/a_0)$ where R is the linear size of the system and a_0 is a short-distance cutoff (see Section “Vortices in two dimensions”). However, the situation here is different since the complex scalar field $\phi(x)$ is coupled to a dynamical Chern–Simons gauge field $\mathcal{A}_\mu$. Except for the Chern–Simons nature of this gauge field, the problem we are dealing with is similar to that of a superconductor coupled to a dynamical gauge field or to the Abelian-Higgs model in quantum field theory. In the case of interest, here we have finite energy vortex solutions that satisfy the asymptotic condition

$$\lim_{|x| \rightarrow \infty} |(i\partial_j - \delta\mathcal{A}_j)\phi(x)|^2 = 0 \quad (429)$$

which is obeyed by configurations that obey Eq. (427). Thus, at long distances, the circulation of the Chern–Simons gauge field on a large closed contour Γ that contains the vortex satisfies

$$\oint_{\Gamma} \delta\mathcal{A}_j dx_j = \pm 2\pi. \quad (430)$$

This vortex carries charge. To see this we compute the local charge density $j_0(x)$

$$j_0(x) = -\frac{\delta S_{\text{eff}}}{\delta A_0(x)} = -e \frac{\delta S_{\text{eff}}}{\delta \delta\mathcal{A}_0(x)} = +e \frac{\delta S_{\text{CS}}}{\delta \delta\mathcal{A}_0(x)} = \frac{e}{2\pi m} \epsilon_{ij} \partial_i \delta\mathcal{A}_j(x) \quad (431)$$

and compute the total charge of the vortex on a larger region Σ whose boundary is Γ and obtain

$$Q = e \int d^2x j_0(x) = \frac{e}{2\pi m} \int_{\Sigma} d^2x \epsilon_{ij} \partial_i \delta\mathcal{A}_j(x) = \frac{e}{m} \frac{1}{2\pi} \oint_{\Gamma} dx_j \delta\mathcal{A}_j(x) = \pm \frac{e}{m}. \quad (432)$$

Therefore, the vortex of the composite boson theory has the same charge as the Laughlin quasihole.

To determine the statistics of the vortex, we go back to the effective Lagrangian written in the form of Eq. (409), (from now on we set $\delta\mathcal{A}^\mu \equiv \mathcal{A}^\mu$)

$$\mathcal{L}_{\text{eff}} = \frac{\kappa}{2} (\partial_0 \omega - \mathcal{A}_0)^2 - \frac{\rho_s}{2} (\partial_j \omega - \mathcal{A}_j)^2 + \frac{1}{2\pi} \epsilon_{\mu\nu\lambda} \mathcal{A}^\mu \partial^\nu \mathcal{B}^\lambda - \frac{e}{2\pi} \epsilon_{\mu\nu\lambda} A^\mu \partial^\nu \mathcal{B}^\lambda - \frac{m}{4\pi} \epsilon_{\mu\nu\lambda} \mathcal{B}^\mu \partial^\nu \mathcal{B}^\lambda \quad (433)$$

where A_μ is the external electromagnetic probe field, and where we used units with $\hbar = c = 1$. The first two terms make the statistical gauge field $\mathcal{A}_\mu$ massive. In the low energy limit, the statistical gauge field is frozen to the vortex configurations of the complex scalar field ϕ or, equivalently, to the vortex singularities of its phase field ω . The vorticity current Ω_μ is

$$\Omega_\mu = \epsilon_{\mu\nu\lambda} \partial^\nu \mathcal{A}^\lambda. \quad (434)$$

The effective Lagrangian for the field $\mathcal{B}_\mu$ is

$$\mathcal{L}_{\text{eff}}[\mathcal{B}_\mu] = -\frac{m}{4\pi} \epsilon_{\mu\nu\lambda} \mathcal{B}^\mu \partial^\nu \mathcal{B}^\lambda - \frac{e}{2\pi} A^\mu \epsilon_{\mu\nu\lambda} \partial^\nu \mathcal{B}^\lambda + \Omega_\mu \mathcal{B}^\mu \quad (435)$$

which, except for the coupling to the electromagnetic field, has the same form as in Eq. (224), and of the effective action introduced in Section “Hydrodynamic effective field theory” on phenomenological grounds.

The effective topological field theory of Eq. (435) encodes all the *universal* data of fractional quantum Hall fluids. Being topological, this effective field theory has no energy scales and describes the physics at energies low compared to any excitation energy gap. In addition to yielding the correct Hall conductivity $\sigma_{xy} = \nu e^2/h$ (with $\nu = 1/m$) and the fractional vortex charge $Q = e/m$, this theory will allow us to draw important additional results about the low energy physics.

By using the results of Section “Fractional statistics and braids,” we conclude that the vortices of the composite boson are anyons with fractional statistics $\exp(\pm i\pi/m)$, consistent with the conclusions of Section “Quasiholes have fractional statistics.” In addition, on a 2-torus the ground state of this system is m -fold degenerate. This feature, characteristic of systems with *topological order*, is that the ground state degeneracy depends on the topology of the surface on which the 2DEG resides. The ground state on a torus degeneracy was shown by Haldane and Rezayi (1985) by an explicit construction of a model wave function for the Laughlin states on a torus. On a surface with g handles (i.e., genus g), the degeneracy is m^g . Wen and Niu (1990) showed that these results hold for any FQH state which are, quite generally, topological quantum fluids.

Finally, we may ask how many *distinct* types of vortices does this theory have. The fundamental (Laughlin) vortex has charge e/m and statistics π/m . In principle we could have a vortex with any integer topological charge (winding number) $n \in \mathbb{Z}$. Such a vortex has charge ne/m and statistics $\pi n^2/m$. However, a vortex with topological charge $n = m$ has charge e and statistics $m\pi$. This vortex is indistinguishable from a hole (a missing electron) since it has the same charge and statistics. We conclude that a Laughlin state has m distinct vortices with $n = 1, 2, \dots, m-1$. We notice that this number is the as the number of degenerate states on a torus. In Section “Fractional quantum hall wave functions and conformal field theory,” we will see that this fact is closely related to the number of primary fields of a CFT associated with the FQH states.

Composite fermion field theory

At the beginning of Section “Composite Boson field theory,” we noted that flux attachment can be used to define equivalent theories: (a) by attaching an *odd* number, m , fluxes to each electron thereby becoming a composite boson, and (b) by attaching an *even* number, $m-1$, fluxes by which the electrons turn into *composite fermions*, as in Jain’s construction (Jain, 1989b). In this section we discuss the most salient features of the field theory approach to composite fermions, introduced by López and Fradkin (1991, 1993) as a theory of all the Jain states. This approach was extended in 1993 by Halperin et al. (1993) to the case of the compressible states.

By following the same approach that we used in Section “Composite Boson field theory,” but adapted to the case in which we map to a theory of a composite Fermi field $\psi(x)$, we find their dynamics is described by the effective action (López and Fradkin, 1991)

$$\begin{aligned} \mathcal{S}_{\text{CF}} = & \int d^3x \left\{ \psi^*(x) [iD_0 + \mu] \psi(x) + \frac{1}{2M} |D\psi(x)|^2 \right\} + \frac{1}{4\pi n} \int d^3x \epsilon_{\mu\nu\lambda} \mathcal{A}^\mu \partial^\nu \mathcal{A}^\lambda \\ & - \frac{1}{2} \int d^3x \int d^3x' (|\psi(x)|^2 - \rho_0) V(x - x') (|\psi(x')|^2 - \rho_0) \end{aligned} \quad (436)$$

where $n = m - 1$ is an even integer. Here $V(x - x') = \delta(x_0 - x'_0) V(|\mathbf{x} - \mathbf{x}'|)$ is the instantaneous electron–electron repulsive interaction, and ρ_0 is the average areal neutralizing charge density. As before, the covariant derivative is $D_\mu = \partial_\mu + ieA_\mu + \mathcal{A}_\mu$, where A_μ is the electromagnetic field (including the uniform magnetic field B), and $\mathcal{A}_\mu$ is the statistical gauge field. We are using units such that $\hbar = c = 1$.

We can simplify somewhat the form of the actions for the composite fermions by using the fact that the Gauss law of Chern–Simons gauge theory states that the particle density and the gauge flux are rigidly tied together, $|\psi(x)|^2 = \frac{1}{2\pi n} \mathcal{B} \equiv \epsilon_{ij} \partial_i \mathcal{A}_j$ (this is the flux attachment) as an operator identity. Thus, we can write the action as

$$\begin{aligned} \mathcal{S}_{\text{CF}} = & \int d^3x \left\{ \psi^*(x) [iD_0 + \mu] \psi(x) + \frac{1}{2M} |D\psi(x)|^2 \right\} + \frac{1}{4\pi n} \int d^3x \epsilon_{\mu\nu\lambda} \mathcal{A}^\mu \partial^\nu \mathcal{A}^\lambda \\ & - \frac{1}{2} \int d^3x \int d^3x' \left(\frac{\mathcal{B}(x)}{2\pi n} - \rho_0 \right) V(x - x') \left(\frac{\mathcal{B}(x')}{2\pi n} - \rho_0 \right). \end{aligned} \quad (437)$$

Since this action is a quadratic form in the Fermi (Grassmann) fields ψ , we can integrate them out to obtain the following effective action for the statistical gauge field $\mathcal{A}_\mu$

$$\mathcal{S}_{\text{eff}}[\mathcal{A}_\mu] = -i\text{tr} \left(iD_0 + \mu + \frac{D^2}{2M} \right) + \frac{1}{4\pi n} \int d^3x \epsilon_{\mu\nu\lambda} (\mathcal{A}^\mu - eA^\mu) \partial^\nu (\mathcal{A}^\lambda - eA^\lambda) + \mathcal{S}_{\text{int}}[\mathcal{A}_\mu - eA_\mu] \quad (438)$$

where A_μ is a probe external electromagnetic field (with vanishing average) and does not include the uniform magnetic field. The interaction term is

$$\mathcal{S}_{\text{int}}[\mathcal{A}_\mu - eA_\mu] = -\frac{1}{2} \int d^3x \int d^3x' \left(\frac{(\mathcal{B}(x) - eB(x))}{2\pi n} - \rho_0 \right) V(x - x') \left(\frac{(\mathcal{B}(x') - eB(x'))}{2\pi n} - \rho_0 \right). \quad (439)$$

Here too $B(x)$ is an external probe with vanishing average.

We will investigate the properties of the path integral for the statistical gauge field

$$Z[A_\mu] = \int \mathcal{D}\mathcal{A}_\mu \exp(i\mathcal{S}_{\text{eff}}[\mathcal{A}_\mu, A_\mu]) \quad (440)$$

using a saddle point expansion. The saddle-point condition of the effective action of Eq. (438)

$$\frac{\delta \mathcal{S}_{\text{eff}}}{\delta \mathcal{A}_\mu(x)} = 0 \quad (441)$$

leads to the equation of motion for the field $\mathcal{A}_\mu$

$$\langle j_\mu^F(x) \rangle + \frac{1}{4\pi n} \epsilon_{\mu\nu\lambda} [\mathcal{F}^{\nu\lambda}(x) - eF^{\nu\lambda}] = 0 \quad (442)$$

where $\langle j_\mu^F \rangle$ is the expectation value of the fermionic current. In addition we need to impose the condition for the particle density to be uniform and equal to the neutralizing background charge $\langle j_0^F(x) \rangle = \rho_0$.

We will assume that the electromagnetic field A_μ describes just a static uniform magnetic field of strength B . Under these conditions, the ground state should also be static and uniform. This means that the field strength of the statistical gauge field should be constant and uniform value $\langle \mathcal{B} \rangle$, and that the current $\langle j^F \rangle$ should vanish in the ground state. On the other hand, the Gauss Law of the Chern–Simons gauge field implies that $\langle \mathcal{B} \rangle = -2\pi n \rho_0$ while the zero current condition requires the (statistical) electric field vanishes, $\langle \mathcal{E} \rangle = 0$. Since the composite fermion couples in the same way to the electromagnetic field A_μ and to the statistical field $\mathcal{A}_\mu$ we conclude that they experience an effective magnetic field

$$B_{\text{eff}} = B + \frac{1}{e} \langle \mathcal{B} \rangle = B - 2\pi n \frac{\rho_0}{e}. \quad (443)$$

If the total number of electrons is N , then $\rho_0/e = N/L^2$, where L is the linear size of the system. Let us denote by N_ϕ^{eff} the total number of flux quanta of the effective magnetic field (in units of $\hbar = c = 1$ in which the flux quantum is $\phi_0 = 2\pi$), and $2\pi N_\phi = BL^2$ is the total flux. Then, the total effective flux is

$$2\pi N_\phi^{\text{eff}} = 2\pi N_\phi - 2\pi n N. \quad (444)$$

Let $v = N/N_\phi$ be the filling fraction and $v^{\text{eff}} = N/N_\phi^{\text{eff}}$ be the effective filling fraction. Eq. (444) implies that these filling fractions are related by

$$\frac{1}{v^{\text{eff}}} = \frac{1}{v} - n. \quad (445)$$

Recall that n is an *even* integer. However, the system will be incompressible only if $v^{\text{eff}} = p \in \mathbb{Z}$. In other words, the composite fermions fill an integer number p of the partially screened Landau levels, which is Jain's condition. For this condition to be satisfied, the filling fraction $v(p, n)$ is

$$v_\pm(n, p) = \frac{p}{np \pm 1} \quad (446)$$

which are the Jain fractions. In the special case $p = 1$, the Jain fractions are the Laughlin fractions, with $n = m - 1$. Similarly we find that B_{eff} is

$$B_{\text{eff}} = \pm \frac{B}{np \pm 1}. \quad (447)$$

So we see that the external field B is partially screened to the smaller value B_{eff} which can be parallel (screened) to B or antiparallel (overscreened) to B . For the same reason, at this mean field level, the cyclotron frequency ω_c is reduced by the same amount to $\omega_c^{\text{eff}} = \omega_c/(np \pm 1)$.

We will discuss now the effects of quantum fluctuations for the action of Eq. (438) about the saddle-point solutions. We will work to the lowest order (quadratic) in the fluctuations, which can be regarded as a semiclassical (or "RPA") treatment of this theory. The quadratic effective action for the fluctuations of statistical gauge field, which we will still denote by $\mathcal{A}_\mu$ is

$$\begin{aligned} S_{\text{eff}}^{(2)}[\mathcal{A}_\mu] &= \frac{1}{2} \int d^3x \int d^3y \mathcal{A}^\mu(x) \Pi_{\mu\nu}^{\text{CF}}(x, y) \mathcal{A}^\nu(y) \\ &\quad + \frac{1}{4\pi n} \int d^3x \epsilon_{\mu\nu\lambda} (\mathcal{A}_\mu(x) - eA_\mu(x)) \partial^\nu (\mathcal{A}_\nu(x) - eA_\nu(x)) + S_{\text{int}}(\mathcal{A}_\mu - eA_\mu). \end{aligned} \quad (448)$$

Here, $\Pi_F^{\mu\nu}(x, y)$ is the polarization tensor of the composite fermions for p -filled effective Landau levels. The interaction term of the action is given in Eq. (439).

As required by gauge invariance, the composite fermion polarization tensor is transverse, $\partial^\mu \Pi_{\mu\nu}^{\text{CF}} = 0$, which fixes the tensorial structure. In momentum and frequency space, the composite fermion polarization tensor $\Pi_{\mu\nu}^{\text{CF}}(\mathbf{q}, \omega)$ depends on three kernels $\Pi_0^{\text{CF}}(\mathbf{q}, \omega)$, $\Pi_1^{\text{CF}}(\mathbf{q}, \omega)$, and $\Pi_2^{\text{CF}}(\mathbf{q}, \omega)$, where Π_0^{CF} and Π_2^{CF} contain the parity-even response of the composite fermions and Π_1^{CF} is their parity-odd response. Each kernel is given as a series terms representing particle-hole processes with simple poles at the excitations energies $\omega_{rs} = (r-s)\omega_c^{\text{eff}}$, with $r > p$ (particles) and $s \leq p$ (holes). Each term has a residue, which is an integer power of q^2 times a Laguerre polynomial in q^2 . Details of these kernels can be found in López and Fradkin (1991) and in Chapter 13 of Fradkin (2013). However, what will be important here is that, in the gapped states these kernels have a low energy and low momentum limit which is local. This will enable us to find a local topological effective action only for the gapped states.

After integrating out the statistical gauge field $\mathcal{A}_\mu$, we find the effective action for the external electromagnetic probe field A_μ , which has the standard form

$$S_{\text{eff}}[A_\mu] = \frac{1}{2} \int d^3x \int d^3y A_\mu(x) \Pi^{\mu\nu}(x - y) A_\nu(y) \quad (449)$$

which encodes the full electromagnetic response of the system, not just of the composite fermions. Once again, gauge invariance requires that the full polarization tensor be transverse, $\partial^\mu \Pi_{\mu\nu} = 0$.

In Section "The quantum Hall effect on a lattice," we showed that there is a relation between the polarization tensor $\Pi_{\mu\nu}$ and the current-current correlation function $\mathcal{D}_{\mu\nu}$. There we mentioned that these correlators are required (by gauge invariance) to satisfy a Ward-Takahashi identity known as the f-sum rule:

$$\int_{-\infty}^{\infty} \frac{d\omega}{2\pi} i\omega \mathcal{D}_{00}^R(\omega, \mathbf{q}) = \frac{\rho_0}{M} q^2 \quad (450)$$

where the (retarded) density-density correlation function is related to the (retarded) polarization tensor, $\mathcal{D}_{00}^R(\omega, \mathbf{q}) = \Pi_{00}^R(\omega, \mathbf{q})$. In the limit of low momentum $\mathbf{q}$, at fixed frequency ω , the expression for $\Pi_{00}^R(\omega, \mathbf{q})$ is

$$\Pi_{00}^R(\omega, \mathbf{q}) \simeq q^2 \Pi_0^R(\omega, \mathbf{q}) = -\frac{\rho_0}{M} \frac{q^2}{(\omega + i\epsilon)^2 - \omega_c^2} \quad (451)$$

where $\omega_c = eB/(Mc)$ is the cyclotron frequency of the *electrons*. This expression saturates the sum rule. This means that whichever corrections Eq. (451) may have must vanish in the low $\mathbf{q}$ limit. In other words, in this limit, the approximation that we made is actually exact. This is well-known result in the theory of the FL (Nozières and Pines, 1966).

In addition, the result of Eq. (451) implies that there is a particle–hole (density) collective mode which at low momentum has energy $\hbar\omega_c$, without corrections. This result is known as Kohn’s theorem (Kohn, 1961), which states that in a Galilean invariant system, the 2DEG must have an exact eigenstate at the cyclotron frequency. More intuitively, the center of mass of the 2DEG executes a cyclotron motion regardless of whether the particles are free, interacting or not, fermions, bosons, or anyons. This is a general result. Notice that the composite fermions do not satisfy Kohn’s theorem as the cyclotron mode would be at the effective cyclotron frequency ω_c^{eff} , and that the leading quantum fluctuations have restored the magnetic symmetry.

In the limit of low energy $\omega \rightarrow 0$ and low momentum $q \rightarrow 0$ of the kernels Π_0^{CF} , Π_1^{CF} and Π_2^{CF} become

$$\Pi_0^{\text{CF}}(0,0) = \frac{p}{2\pi} \frac{M}{B_{\text{eff}}} \equiv \varepsilon^{\text{CF}}, \quad \Pi_1^{\text{CF}}(0,0) = \pm \frac{p}{2\pi} \equiv \sigma_{xy}^{\text{CF}}, \quad \Pi_2^{\text{CF}}(0,0) = -\frac{1}{2\pi} \frac{p^2}{M} \equiv -\chi^{\text{CF}} \quad (452)$$

where ε^{CF} is the “dielectric constant” of the composite fermions, χ^{CF} is their effective “permeability,” and σ_{xy}^{CF} is the (integer) composite fermion Hall conductivity. We then find that low-energy effective action of the statistical gauge field $\mathcal{A}_\mu$ is

$$\begin{aligned} S_{\text{eff}}[\mathcal{A}_\mu] = & \frac{1}{2} \left(\sigma_{xy}^{\text{CF}} + \frac{1}{2\pi n} \right) \int d^3x \epsilon_{\mu\nu\lambda} \mathcal{A}^\mu(x) \partial^\nu \mathcal{A}^\lambda(x) \\ & - \frac{e}{2\pi n} \int d^3x \epsilon_{\mu\nu\lambda} \mathcal{A}^\mu(x) \partial^\nu A^\lambda(x) + \frac{e^2}{4\pi n} \int d^3x \epsilon_{\mu\nu\lambda} A^\mu(x) \partial^\nu A^\lambda(x) \\ & + \int d^3x \frac{1}{2} (\varepsilon^{\text{CF}} \mathcal{E}_i^2(x) - \chi^{\text{CF}} \mathcal{B}^2(x)) \\ & - \frac{1}{8\pi^2 n^2} \int d^3x \int d^3y (\mathcal{B}(x) - eB(x)) V(x-y) (\mathcal{B}(y) - eB(y)). \end{aligned} \quad (453)$$

Notice that, except possibly for the last term, the effective action is a local. This is possible because the mean field theory state is gapped.

In what follows we will focus only on the leading terms of the effective action and neglect the subleading terms, the least two terms of the effective action which have the form of a Maxwell term and an additional (possibly nonlocal) term. The remaining leading terms have a Chern–Simons form and a BF form whose effective Lagrangian is

$$\mathcal{L}_{\text{eff}}[\mathcal{A}_\mu] = \frac{1}{4\pi} \left(\pm p + \frac{1}{n} \right) \epsilon_{\mu\nu\lambda} \mathcal{A}^\mu(x) \partial^\nu \mathcal{A}^\lambda(x) - \frac{e}{2\pi n} \epsilon_{\mu\nu\lambda} \mathcal{A}^\mu(x) \partial^\nu A^\lambda(x) + \frac{e^2}{4\pi n} \epsilon_{\mu\nu\lambda} A^\mu(x) \partial^\nu A^\lambda(x). \quad (454)$$

If integrating the statistical gauge field $\mathcal{A}_\mu$ we find the electromagnetic field A_μ has the effective Lagrangian

$$\mathcal{L}_{\text{eff}}[A_\mu] = \frac{\sigma_{xy}}{2} \epsilon_{\mu\nu\lambda} A_\mu(x) \partial^\nu A_\lambda(x) \quad (455)$$

from where we find that the Hall conductivity σ_{xy} of the 2DEG is

$$\sigma_{xy} = \frac{e^2}{2\pi\hbar} \frac{p}{pn \pm 1} \quad (456)$$

which is the Hall conductivity of the Jain states (in standard units). Here, as before, n is an even integer.

We will now return to the effective Lagrangian of Eq. (454). As it stands, since the Chern–Simons term has fractional level, it is not invariant under large gauge transformations and, as such, cannot be defined on a closed manifold. To remedy this problem, we can now write this Lagrangian in terms of a theory with two dynamical gauge fields $\mathcal{A}_\mu$ and $\mathcal{B}_\mu$ as follows:

$$\begin{aligned} \mathcal{L}_{\text{eff}}[\mathcal{A}_\mu, \mathcal{B}_\mu] = & \frac{p}{4\pi} \epsilon_{\mu\nu\lambda} \mathcal{A}^\mu(x) \partial^\nu \mathcal{A}^\lambda(x) - \frac{n}{4\pi} \epsilon_{\mu\nu\lambda} \mathcal{B}^\mu(x) \partial^\nu \mathcal{B}^\lambda(x) \\ & + \frac{1}{2\pi} \epsilon_{\mu\nu\lambda} \mathcal{A}^\mu(x) \partial^\nu \mathcal{B}^\lambda(x) - \frac{e}{2\pi} \epsilon_{\mu\nu\lambda} \mathcal{B}^\mu(x) \partial^\nu A^\lambda(x) \end{aligned} \quad (457)$$

This is a topological quantum field theory for all the Jain states (López and Fradkin, 1999). This theory can be defined on any manifold no matter its topology. It is easy to see that upon integrating out the field $\mathcal{B}_\mu$ we recover the effective field theory for $\mathcal{A}_\mu$ of Eq. (454). Also, in the special case of the Laughlin states, for which $p = 1$, we can integrate out the field $\mathcal{A}_\mu$ and arrive to the effective topological field theory for the field $\mathcal{B}_\mu$ of Eq. (435) that we derived in the composite boson theory in Section “Composite Boson field theory.”

Let us rewrite the Lagrangian of Eq. (457) in a more compact yet general form. To this end, we define a multicomponent gauge field $\mathcal{A}_\mu^I$ with $I = 1, \dots, L$, an L -component charge vector t , and an $L \times L$ second rank symmetric matrix K_{IJ} . Wen and Zee have given a general classification of a large class of fractional quantum Hall states, said to be *abelian*, whose topological field theory is defined by the Lagrangian (Wen and Zee, 1992; Wen, 1995)

$$\mathcal{L} = \frac{1}{4\pi} K_{IJ} \epsilon^{\mu\nu\lambda} \mathcal{A}_\mu^I(x) \partial^\nu \mathcal{A}_\lambda^J(x) - \frac{e}{2\pi} t_I \epsilon^{\mu\nu\lambda} A_\mu(x) \partial^\nu \mathcal{A}_\lambda^I(x). \quad (458)$$

In the case of the theory of Eq. (457) which has two components, $L = 2$, with $\mathcal{A}_\mu^1 = \mathcal{A}_\mu$ and $\mathcal{A}_\mu^2 = \mathcal{B}_\mu$. The two-component vector is $t = (0, 1)$ and the matrix 2×2 matrix is

$$K = \begin{pmatrix} -p & 1 \\ 1 & n \end{pmatrix}. \quad (459)$$

Wen and Zee showed that, quite generally, a theory of the K -matrix form has a vacuum degeneracy on a torus of $|\det K|$ and, on a surface of genus g , the degeneracy is $|\det K|^g$. They also showed that the Hall conductivity is $\sigma_{xy} = \nu e^2/h$ where the filling fraction is

$$\nu = \sum_{I,J=1}^L t_I K_{IJ}^{-1} t_J. \quad (460)$$

The properties of the quasiparticles can be determined by computing the appropriate correlator. In the composite fermion theory, whose Lagrangian is given in Eq. (437), the *gauge-invariant* composite fermion propagator is

$$G_{CF}(x - y; \gamma(x, y)) = \left\langle \psi^\dagger(x) \exp(i \int_{\gamma(x,y)} dz_\mu (eA_\mu(z) + \mathcal{A}^\mu)) \psi(y) \right\rangle \quad (461)$$

which, as in any gauge theory, it is gauge-invariant but path-dependent. Here γ is an oriented open path with endpoints that the space-time locations x and y . The composite fermion propagator has information about many of the properties of the quasiparticles, including their electric charge. To find what is the statistics of the quasiparticles, we need to compute a two-particle correlator (a four-point function), which is defined in terms of two open oriented paths, say $\gamma_1(x, y)$ and $\gamma_2(u, w)$, with endpoints at the locations of the two particles, respectively.

The computation of these correlators is done using a feynman sum over trajectories with different weights, which depend on the gauge field configurations. To do these calculations is, in general, a complicated problem. However, in a gapped state, the quasiparticles are massive and in the low-energy regime, these expressions are dominated by a classical trajectory on an oriented path $\tilde{\gamma}(x, y)$ with the same endpoints x and y . The end result reduces to the computation of the expectation value of a Wilson loop operator

$$W[\Gamma] = \left\langle \exp(i \oint_\Gamma dz_\mu (eA_\mu(z) + \mathcal{A}^\mu(z))) \right\rangle_{\mathcal{A}^\mu} \quad (462)$$

on the *closed* oriented path $\Gamma = \gamma \cup \tilde{\gamma}^-$ (where $\tilde{\gamma}^-(y, x)$ has the opposite orientation as $\tilde{\gamma}(x, y)$ and runs from y to x). The explicit dependence on the external electromagnetic field yields the value of the charge of the quasiparticle through the Aharanov-Bohm effect. Likewise, the two-particle correlator is reduced, in the asymptotic low-energy regime, to the computation of an expectation value of two Wilson loops in the effective Chern–Simons theory, as was done in Section “Fractional statistics and braids,” which yields the fractional statistics of the quasiparticles. The interested reader can find details in Chapter 13 of [Fradkin \(2013\)](#).

A system described by a theory of the form of Eq. (458) has different types of quasiparticles. In general we can assign an integer-valued quantum number $\ell_I \in \mathbb{Z}$ as the charge of the quasiparticle with respect to the gauge field $\mathcal{A}_I^\mu$. The general coupling of a quasiparticle current has the form $\mathcal{L}_{qp} = j_\mu \ell_I \mathcal{A}_I^\mu$. Then, the charge $Q[\ell]$ and the statistics $\delta[\ell]$ of a general quasiparticle defined by the integer-valued L -component vector ℓ are

$$Q[\ell] = -e t_I K_{IJ}^{-1} \ell_J, \quad \frac{\delta[\ell]}{\pi} = \ell_I K_{IJ}^{-1} \ell_J + 1 \quad (463)$$

where +1 is required to refer the statistics to fermions (not bosons) ([López and Fradkin, 1999](#)). These results are general and hold for any Abelian FQH state ([Wen and Zee, 1992](#)).

In the case of the Jain states, the charge vector is $t = (0, 1)$ and the quasiparticle is labeled by the vector $\ell = (1, 0)$, which yield the results for the charge Q and the statistics δ

$$Q = \frac{-e}{np + 1}, \quad \delta = \pi \left(\frac{-n}{np + 1} + 1 \right) \quad (464)$$

which are the quantum numbers of the quasiparticles of the Jain states. For the Laughlin state at $\nu = 1/3$, we obtain $Q = -e/3$ and $\delta = \pi/3$ (as we should), which for the first Jain state at $\nu = 2/5$, the charge Q , and the statistics δ are $Q = -e/5$ and $\delta = 3\pi/5$. With some caveats, the predictions for the quasiparticle charge in the FQH states with $\nu = 1/3$ and $\nu = 2/5$ have been confirmed in noise measurements at a quantum point contact by [de Picciotto et al. \(1997\)](#) and by [Saminadayar et al. \(1997\)](#). Fractional statistics has been measured experimentally in both FQH states at $\nu = 1/3$ and $\nu = 2/5$ in (Fabry-Perot) interferometers by [Nakamura et al. \(2020\)](#).

The compressible states

At large values $p \rightarrow \infty$, the Jain sequences converge to the even-denominator fractions $\nu_\infty(n) = 1/n$. In this limit, $B_{\text{eff}} \rightarrow 0$ and $\omega_c^{\text{eff}} \rightarrow 0$. In other words, at the filling fractions $\nu_\infty(n)$, the average effective field experienced by the composite fermions is zero. This mean field theory then would predict that this state is essentially a FL of composite fermions which is a compressible state. In addition, one can compute the effective charge of the composite fermion and find that it is $e/(np \pm 1)$, which also vanishes in the compressible limit. It is straightforward to see that the Fermi sea of the composite fermions is a disk with Fermi momentum

$p_F = (2v_\infty(n))^{1/2} \hbar / \ell_0$ and that the Fermi energy is $E_F = v_\infty(n) \hbar / (M \ell_0^2)$. Halperin et al. (1993) did an in-depth analysis of the consequences of this compressible state, which are largely in agreement with experiment.

In our discussion of the incompressible FQ states, both in the composite boson and in the composite fermion approaches in Sections “Composite Boson field theory” and “Composite fermion field theory,” we saw that the mean field approximation violated symmetries that were restored by quantum fluctuations. This fact allowed us to derive effective field theories which are asymptotically exact in the low energy IR regime. What allowed us to obtain these exact results is the existence of a gap. However, the compressible states are gapless and in some sense should be regarded theories of a quantum critical system.

In fact, if we reexamine the field theory of composite fermions of Section “Composite fermion field theory,” we see that, in the compressible limit $p \rightarrow \infty$, the action of Eq. (437) describes a system of fermions at finite density coupled to the fluctuations $\mathcal{A}_\mu$ of the statistical gauge field with a Chern–Simons term, but without an external uniform field (which has been canceled by the flux of the average statistical gauge field). This theory has two salient features. One is that the only trace left of the explicitly broken time-reversal symmetry is in the presence of the Chern–Simons term. This means that while the mean field theory looks like a FL, the consequences of the broken time-reversal invariance only enters in the quantum fluctuations. In addition, in this regime, this theory also breaks the particle–hole symmetry of a half-filled Landau level (in the high magnetic field regime).

However, these contributions, already at one-loop order, typically contain IR divergencies. These IR divergencies are due to singular forward scattering processes of the composite fermions by the gauge fields. They are most severe in the computation of the fermion self energy and depend on the form of the electron–electron interactions. For instance if the interaction potential $V(R)$ is short range, the one-loop contribution to the fermion self-energy has an imaginary part with the behavior $\Sigma''(\omega) \sim \omega^{2/3}$, which is much larger than the real part $\Sigma'(\omega)$ as $\omega \rightarrow 0$ and the Fermi energy E_F is approached (Halperin et al., 1993). This behavior, which is found in many metallic systems at quantum criticality (Hertz, 1976; Millis, 1993; Sachdev, 2011), implies that the width of the quasiparticle is asymptotically much larger than the energy as the Fermi surface is approached. This one-loop result means that perturbation theory fails in the IR and that actual behavior may be nonperturbative. This problem is present even in the case of unscreened $\frac{e^2}{R}$ (Coulomb) interactions where the singular behavior is milder with $\Sigma''(\omega) \sim \omega \ln \omega$ [known as Marginal Fermi Liquid scaling (Varma et al., 1989)].

At any rate, these IR singular behaviors imply that the quasiparticle picture is inadequate and that in these regimes there may be no quasiparticles. These systems are generally known as “Strange Metals.” Many strongly interacting physical systems of interest, ranging from high T_c superconductors to (largely conjectured) spin liquids with spinon Fermi surfaces to even quark-gluon plasmas, share these types of singular IR behaviors (Varma et al., 1989; Polchinski, 1994). In spite of a large body of theoretical work, it has remained largely unsolved problem. Perturbative renormalization group methods used to justify the Landau theory of the Fermi liquid (Shankar, 1994; Polchinski, 1993) generally fail in these regimes, although in some cases long-range interactions have allowed some degree of control (Nayak and Wilczek, 1994a, b). Remarkably, the AdS/CFT Gauge/Gravity Duality (Maldacena, 1998) has brought new insights into strange metal behaviors (Faulkner et al., 2010). We will see below that relativistic dualities have given additional insights into the physics of compressible states.

Fractional quantum hall wave functions and conformal field theory

The Laughlin wave function and its generalizations share the remarkable feature of being essentially universal. Aside from the dependence on the magnetic length ℓ_0 in the Gaussian factors, which ensure that the function is integrable at long distances (a feature inherited from the single-particle states in the Landau level), the FQH “ideal” wave functions do not have any length scales. In addition, in almost all cases, the ideal wave functions are the exact ground state wave functions of some suitable ultra-local Hamiltonian projected onto the lowest Landau level. Another feature, closely related to their universality and analyticity, is that these wave functions look similar to correlation functions in two-dimensional critical (chiral) critical systems. We will now see that these features are not accidental and point to a deep relation between quantum Hall states and CFT.

Although the relation between the simpler case of the Laughlin state was known to several people, such as Fubini (1991), this deep connection with rational CFT was articulated in considerable generality in a somewhat earlier paper by Moore and Read (1991). This approach showed its full power in the formulation of the non-Abelian quantum Hall states.

Let us begin with the simpler case of the Laughlin states with $\nu = 1/m$, where m is odd for fermions and even for bosons. We will consider a $U(1)$ Euclidean CFT of a compact boson (a scalar field) $\phi(x)$ closely related to our discussion of bosonization in 1+1 dimensions in Section “Bosonization, anomalies, and duality.” This theory has been extensively studied in the CFT literature (Ginsparg, 1989; Di Francesco et al., 1997; Polchinski, 1998). The Euclidean action for this theory is

$$S = \frac{1}{8\pi} \int d^2x (\partial_\mu \phi)^2. \quad (465)$$

This theory is compactified by the condition that the only allowed observables are invariant under the discrete symmetry

$$\phi(x) \mapsto \phi(x) + 2\pi Rn \quad (466)$$

where R is the compactification radius and n is an arbitrary integer. The observables that satisfy this condition are vertex operators of the form

$$V_p(x) = \exp\left(i\frac{p}{R}\phi(x)\right) \quad (467)$$

where p is an integer.

The correlators of this theory are products of holomorphic (right-moving in Minkowski spacetime) and antiholomorphic (left-moving in Minkowski spacetime) factors. In the context of the FQH states, we will be interested in a chiral theory, whose correlators are holomorphic (analytic) functions in complex coordinates $z = x_1 + ix_2$. Formally, the field $\phi(z, \bar{z})$ is decomposed into a sum of a holomorphic field $\phi(z)$ and antiholomorphic field $\phi(\bar{z})$ so that the propagator is

$$\langle \phi(z, \bar{z}) \phi(w, \bar{w}) \rangle = -\ln(z - w) - \ln(\bar{z} - \bar{w}). \quad (468)$$

In what follows we will focus on the chiral(holomorphic) field $\phi(z)$ whose propagator is

$$\langle \phi(z) \phi(w) \rangle = -\ln(z - w). \quad (469)$$

The correlator of the chiral current operator

$$j(z) = \frac{i}{R} \partial_z \phi(z) \quad (470)$$

is given by

$$\langle i\partial_z \phi(z) i\partial_w \phi(w) \rangle \sim \frac{1}{(z - w)^2} \quad (471)$$

which tells us that this operator has (chiral) scaling dimension $\Delta = 1$. Similarly the correlator of two *chiral* vertex operators

$$V_p(z) = \exp\left(i\frac{p}{R}\phi(z)\right) \quad (472)$$

is

$$\langle V_p(z) V_{-p}(w) \rangle = \frac{1}{(z - w)^{p^2/R^2}} \quad (473)$$

whose (chiral) scaling dimension is $\Delta_p = p^2/(2R^2)$. These expressions are very similar to the operators that we used in Section “Vortices in two dimensions” to describe vortices in 2D superfluids (and planar magnets). The main difference is that here the fields and their correlators are holomorphic where in Section “Vortices in two dimensions” the correlators are the product of a holomorphic and antiholomorphic factors.

For general p and R , the correlator of Eq. (473) has a branch cut from z to w . This means that the *monodromies* of the operators, that is, dragging an operator around the other, induce a change in the *phase* of the correlator equal to $2\pi p^2/R^2$. This behavior is reminiscent of the analytic structure of the quasiparticle wave function in the FQH states and of the *braiding* operation between anyons.

Moore and Read (1991) showed that the following correlator in a $U(1)$ compactified boson CFT (with compactification radius $R = \sqrt{m}$) is equal to the Laughlin wave function at filling fraction $\nu = 1/m$,

$$\Psi_m(z_1, \dots, z_N) = \left\langle \left(\prod_{i=1}^N \exp(i\sqrt{m}\phi(z_i)) \right) \exp\left(-i \int d^2z' \sqrt{m} \rho_0 \phi(z')\right) \right\rangle \quad (474)$$

$$= \prod_{i < j} (z_i - z_j)^m \exp\left(-\frac{1}{4} \sum_{i=1}^N |z_i|^2\right) \quad (475)$$

where we have used units in which the magnetic length is $\ell_0 = 1$.

In Section “Vortices in two dimensions,” we saw that correlators of vertex operators are nonvanishing only if their total charge (vorticity) is zero. The reason for this condition is that the (Euclidean) action is invariant under arbitrary uniform shifts of the field ϕ . Now, in the correlator on the right-hand side of Eq. (475), we have a product of N vertex operators, each with the same charge $\sqrt{m}$. Then, under an arbitrary shift by α of the field $\phi(z)$, the product of vertex operators changes by a phase equal to $N\sqrt{m}\alpha$. On the other hand the other operator in the correlator, which describes a continuum background charge, changes by a phase $-\sqrt{m}\rho_0 L^2 \alpha$, where L^2 is the area. Since ρ_0 is the areal particle density, N/L^2 , the two changes of the phase cancel each other exactly. Thus, the operator in the expectation value of Eq. (475) is charge neutral and has a nonvanishing expectation value.

The other important feature of the correlator of Eq. (475) is the choice of compactification radius, $R = \sqrt{m}$, and of the vertex operator $V_p(z)$ with $p = m$:

$$V_m(z) = \exp(i\sqrt{m}\phi(z)) \quad (476)$$

whose correlation function is

$$\langle V_m(z) V_{-m}(w) \rangle = \frac{1}{(z-w)^m}. \quad (477)$$

Which is invariant under a 2π rotation (since $m \in \mathbb{Z}$). However under a rotation by π (i.e., an *exchange*), it changes by $(-1)^m$. Hence, for m odd it changes sign, and the vertex operator V_m behaves as a *fermion*, while for m even the vertex operator behaves as a *boson*. We will call the vertex operator $V_m \equiv V_e$ the electron operator.

In other words, the correlator of Eq. (475) is the expectation value of N vertex operators, each describing an *electron* (for m odd) and a neutralizing background charge. Then, an elementary calculation yields the expression of the Laughlin wave function.

In this formulation the ground state wave function for the integer QH state at $\nu = 1$, which has the form of a Vandermonde determinant shown in Eq. (377), is interpreted as the correlator of N electron operators in the $U(1)$ CFT with compactification radius $R = 1$. In this simple case, the electron operator is the vertex operator $V_1(z) = \exp(i\phi(z))$, and there are no other operators (aside from the current $j(z) = i\partial_z\phi$). The propagator of this vertex operator is

$$\langle V_1(z) V_{-1}(w) \rangle = \frac{1}{z-w} \quad (478)$$

which indeed represents a fermion with electric charge e .

We will now see that the vertex operator of Eq. (472) with $p = 1$ (and $R = \sqrt{m}$)

$$V_1(z) = \exp\left(\frac{i}{\sqrt{m}}\phi(z)\right) \quad (479)$$

represents the Laughlin quasihole. The correlator of this vertex operator is

$$\langle V_1(z) V_{-1}(w) \rangle = \frac{1}{(z-w)^{1/m}} \quad (480)$$

which has a branch cut stretching from z to w and, as a result, under a rotation by $\pm\pi$, its phase changes by $\pm\pi/m$, just as the Laughlin anyons do. To see that this operator indeed is related to the Laughlin quasihole, we will compute the effect of inserting the vertex operator $V_1(z)$ in the correlator of Eq. (475) and find

$$\begin{aligned} & \left\langle \exp\left(\frac{i}{\sqrt{m}}\phi(w)\right) \left(\prod_{i=1}^N \exp(i\sqrt{m}\phi(z_i)) \right) \exp\left(-i \int d^2z' \sqrt{m} \rho_0 \phi(z')\right) \right\rangle \\ &= \prod_{i=1}^N (z_i - w) \prod_{i < j} (z_i - z_j)^m \exp\left(-\frac{1}{4} \sum_{i=1}^N |z_i|^2 - \frac{1}{4m} |w|^2\right) \\ &= \Psi_m(w; z_1, \dots, z_N) \end{aligned} \quad (481)$$

which is, indeed, the wave function for the Laughlin quasihole of Eq. (392). The insertion of an additional vertex operator $V_1(u)$ at u inside the expectation value of Eq. (481) yields the two-quasihole wave function of Eq. (397), proposed by Halperin (1984) and discussed in Section “Quasiholes have fractional statistics,” with the same branch cut shown in Eq. (398) and, therefore carry fractional statistics π/m .

The operator product expansion discussed in Section “The operator product expansion” of the vertex operators of this CFT yields new insight on the quasiholes. Indeed the OPE of two vertex operators of charges p and q is

$$\lim_{w \rightarrow u} V_p(w) V_q(u) = \lim_{w \rightarrow u} \frac{1}{(w-u)^{\Delta_p + \Delta_q - \Delta_{[p+q]_m}}} V_{[p+q]_m}(u) \quad (482)$$

where $[p]_m$ is the integer p modulo a multiple of m , that is, if $p = mr + s$ (with r a nonnegative integer and $0 \leq s < m$), then $[p]_m = s$. Eq. (482) is understood in the sense that the contribution of all additional operators to the right-hand side vanish as $w \rightarrow u$. In other words, the vertex operators are primary fields of this CFT and there are only m primary fields. The physical process described by the OPE is called *fusion*.

A CFT with a finite number of primaries is called a rational CFT (Ginsparg, 1989; Di Francesco et al., 1997). This result is, of course, the same statement that we made in Section “Composite Boson field theory” that the FQH state has m distinct anyons (vortices). This result also means that a vertex operator of charge m , that is, an electron, is indistinguishable from the *identity operator*, V_0 . In this sense, the allowed primaries are fields that are *local* with respect to the electron operator V_m . From the point of view of the FQH state, an operator that creates or destroys an electron (at fixed filling fraction) has no effect, as the FQH state is a fluid made of electrons. This also means that all physical operators must braid trivially with the electron operator. In a CFT, an operator of this type is said to generate and extend symmetry algebra (Moore and Seiberg, 1989b, a).

Furthermore, the OPE of the chiral current $j(z)$ with the vertex operator $V_1(z)$ is

$$\lim_{w \rightarrow u} j(w) V_1(u) = \frac{1/m}{z-w} V_1(u) \quad (483)$$

which implies that the vertex operator represents a state with charge $1/m$ (in units of the electric charge e).

The CFT approach to construct FQH states has become a very powerful tool. We will see in Section “Edge states and chiral conformal field theory” that FQH states on an open geometry (e.g., a disk) have edge states, which can be understood as chiral CFTs. In addition to providing a deeper understanding of more general Abelian (multicomponent) FQH states with a K -matrix structure, new classes of FQH states with non-Abelian (multidimensional) representations of the Braid Group has been proposed. The anyons of these states are of particular interest since they have been proposed originally by Kitaev in 1997 (Kitaev, 2003) that anyons can be used as physical qubits for topologically protected quantum computation (Kitaev, 2003; Freedman et al., 2002b, a; Preskill, 2004; Das Sarma et al., 2008).

So far, we discussed the case of Abelian anyons. Abelian anyons have the property that the fusion of two anyons is another anyon. Similarly, a braiding operation between two anyons is equivalent (up to a phase factor) to another anyon. Mathematically this means that Abelian anyons are one-dimensional representations of the Braid group. The fractional statistics of an anyon is then a label of the representation of the Braid group. As we saw, the same holds under fusion.

However, the Braid group generally admits multidimensional representations. In this more general case, the fusion (or braiding) of two anyons is represented by a linear combination (superposition) of anyon states. Linear combinations of anyon states are represented by unitary matrices of rank greater than 1. Since matrices generally do not commute braiding and/or fusion processes correspond to a multiplication of these matrices. Such unitary processes are then regarded as quantum gates. This concept is the physical basis of topological quantum computation. It is currently the cutting edge of research in the field.

We will now discuss the simplest non-Abelian FQH states, the Moore-Read (MR) states (Moore and Read, 1991). The Moore-Read wavefunctions are

$$\Psi_{MR}(z_1, \dots, z_N) = \text{Pf} \left(\frac{1}{z_i - z_j} \right) \prod_{i < j} (z_i - z_j)^n \exp \left(-\frac{1}{4\ell_0^2} \sum_{i=1}^N |z_i|^2 \right) \quad (484)$$

which describes an FQH of electrons at filling fraction $\nu = 1/n$, with n an even integer. Here, $\text{Pf}(1/(z_i - z_j))$ is the Pfaffian of the matrix $1/(z_i - z_j)$.

This state was motivated by the discovery of an unexpected FQH state in the $N = 1$ Landau level with an even denominator filling fraction $\nu = 5/2$ by Willett and coworkers in 1987 (Willett et al., 1987; Eisenstein et al., 1988; Pan et al., 2008). Until then, (and since then) this is the only FQH state with an even denominator filling fraction. The Pfaffian factor has a simple pole when two coordinates approach each other. However, provided $n \geq 1$, the “Laughlin factor” in the MR wavefunction cancels the singularity. We will shortly discuss the CFT construction of the Moore-Read state. The poles in the MR wavefunction suggest that in this state the electrons can get closer to each other than in a Laughlin state. This observation suggests that there may be some form of attraction (or suppression of repulsion) between the electrons in the MR state and motivated the notion that the observed even-denominator plateau may be physically related to some sort of pairing interaction. Shortly after the Moore-Read proposal was made, a paired wave function at $\nu = 1/2$ with a Pfaffian factor was also proposed by Greiter et al. (1991, 1992) and Wen (1991) who suggested that it reflects electrons pairing in the $\ell = 1$ angular momentum channel in time-reversal breaking condensate with symmetry $p_x + ip_y$.

Although following the logic behind the Kohn-Luttinger mechanism for pairing in angular momentum state $\ell \geq 1$ with repulsive interactions (Kohn and Luttinger, 1965; Chubukov, 1993; Raghu and Kivelson, 2011), it may be possible to get a paired state even in the lowest Landau level (although there is no evidence for it, so far), the $N = 1$ Landau level may be more hospitable to such a state. Indeed, in the $N = 1$ Landau level the single-particle states i have angular momentum greater or equal than 1, and their probability distributions are suppressed both at short and long distances; these states look like smoke-rings. The matrix elements of the Coulomb potential in the $N = 1$ Landau level are parametrically suppressed at short distances (compared with the states in the lowest, $N = 0$, Landau level). In this scenario, the $\nu = 5/2$ plateau is interpreted as a $\nu = 1/2$ fully polarized state of the $N = 1$ Landau level, with an $N = 0$ Landau level filled with electrons with both spin polarizations in a state with $\nu = 2$. There is numerical evidence that an instability in a p-wave paired state such as the MR state is favored if the short-distance repulsion between the composite fermions is softened (Park et al., 1998).

In fact, in 1983, Halperin (1983) considered generalizations of the Laughlin state in which due to very strong attractive interactions, electrons would form clusters which then condense into a Laughlin-type state. The simplest example was Laughlin state of bosons (paired electrons) a paired state at $\nu = 1/2$ whose Laughlin quasihole carries charge $e/4$. Extensive numerical calculations are more compatible with the MR state than with the Halperin state of pairs (Morf, 1998). We will see shortly that the Halperin state is an Abelian relative of the MR state.

Moore and Read derived the wave function of Eq. (484) by considering a CFT with two sectors: a chiral boson CFT with compactification radius $R = \sqrt{n}$, and a chiral Majorana fermion CFT, i.e. the chiral part of the 2D Ising CFT, discussed in Section “The Ising model in a transverse field.” The chiral Ising CFT has central charge $c = 1/2$ and several primary fields: the identity I , the twist field σ , and the (chiral) Majorana fermion χ with (chiral) scaling dimensions 0, $1/16$, and $1/2$, respectively. The propagator of the Majorana fermion, which is a free field, is

$$\langle \chi(z) \chi(w) \rangle = \frac{1}{z - w}. \quad (485)$$

The primary field σ , the “twist field,” is nonlocal with respect to the Majorana fermion χ , and changes its boundary conditions from periodic to antiperiodic.

The fusion rules of the chiral Ising CFT are

$$\chi \star \chi = I, \quad \sigma \star \sigma = I + \chi, \quad \sigma \star \chi = \chi. \quad (486)$$

What will be important below is that the σ field has two fusion channels. As in the analysis of the Laughlin states, the compactified boson n primaries (anyons), the vertex operators $V_p(x) = \exp(ip\phi(x)/n)$, with $n = 0, 1, \dots, n$ and there are n types of anyons, and a (charge) current $J = \frac{i}{\sqrt{n}} \partial_z \phi(z)$.

The first task is to identify the electron operator, which has to be a fermion and has to carry electric charge. This means that it is a composite of an operator (with Fermi statistics) the (neutral) chiral Ising CFT and a vertex operator whose charge is an integer multiple of e . The desired electron operator is $\psi_e(z) = \chi(z) \exp(i\sqrt{n}\phi(z))$ whose correlator is $\langle \chi(z) V_n(z) \chi(w) V_{-n}(z) \rangle = 1/(z-w)^{1+n}$, which is a fermion with charge e .

The n -point function of the chiral Majorana fermions is

$$\langle \chi(z_1) \dots \chi(z_N) \rangle = \text{Pf} \left(\frac{1}{z_i - z_j} \right) \quad (487)$$

which follows from applying Wick's theorem. Then we see that the MR wave function is the expectation value

$$\Psi_{MR}(z_1, \dots, z_N) = \langle \chi(z_1) \dots \chi(z_N) \rangle \times \left\langle \left(\prod_{i=1}^N \exp(i\sqrt{n}\phi(z_i)) \right) \exp \left(-i \int d^2 z' \sqrt{n} \rho_0 \phi(z') \right) \right\rangle \quad (488)$$

Next we need to identify the primary fields of the tensor product of the chiral Ising CFT, $\mathbb{Z}_2$, and the chiral $U(1)$ CFT with compactification radius $R = \sqrt{n}$. The allowed primary field must be *local* with respect to the electron operator, ψ_e . This leaves us with four primary fields: (a) the identity I , (b) the non-Abelian vortex $\sigma(z) \times \exp\left(\frac{i}{2\sqrt{n}}\phi(z)\right)$ with charge $e/(2n)$ and non-Abelian statistics, (c) the charge-neutral Majorana fermion χ , and (d) the Abelian vortex (the Laughlin quasi-hole) $\exp\left(\frac{i}{\sqrt{n}}\phi(z)\right)$, with charge e/n and Abelian statistics $\delta = \pi/n$.

The new feature here is the non-Abelian fractional statistics of the non-Abelian vortex sometimes called a "half-vortex." Its non-Abelian character is a consequence of the fact that the fusion of two twist fields has two channels, see Eq. (486). This implies that the wave function of four non-Abelian vortices can be expressed as a linear combination of two so-called conformal blocks. In other words, this wave function belongs to a degenerate two-dimensional Hilbert space, each component labeled by a conformal block (Di Francesco et al., 1997). A braiding operation between two non-Abelian vortices is a monodromy of the wave function that induces a unitary transformation U in this Hilbert space

$$U = \frac{1}{\sqrt{2}} \exp \left[i\pi \left(\frac{1}{8} + \frac{1}{4n} \right) \right] \times \begin{pmatrix} 1 & 1 \\ -1 & 1 \end{pmatrix} \quad (489)$$

Therefore, the degenerate Hilbert space of four quasiholes provides a two-dimensional representation of the Braid Group. This observation is the basis for regarding a state of four non-Abelian quasiholes as a qubit. Furthermore, Nayak and Wilczek showed that a state of $2p$ quasiholes spans a 2^{p-1} -dimensional degenerate Hilbert space (Nayak and Wilczek, 1996). This means that, for large p , the degeneracy *per quasi-hole* is $\sqrt{2}$. In other words, this degeneracy is not due to a local degree of freedom attached to each quasi-hole but that it is shared in a nonlocal fashion!

In what sense are the Moore-Read states paired? In an insightful paper Read and Green (2000) used a BCS theory approach to investigate the pairing properties of a condensate of composite fermions in the $p_x + ip_y$ channel. The mean-field BCS Hamiltonian is

$$H_F = \int d^2 k \left[(\varepsilon(\mathbf{k}) - \mu) \psi^\dagger(\mathbf{k}) \psi(\mathbf{k}) + \frac{1}{2} (\Delta^*(\mathbf{k}) \psi(-\mathbf{k}) \psi(\mathbf{k}) + \Delta(\mathbf{k}) \psi^\dagger(\mathbf{k}) \psi^\dagger(-\mathbf{k})) \right] \quad (490)$$

where $\psi(\mathbf{k})$ is the composite fermions field, $\varepsilon(\mathbf{k}) = \frac{k^2}{2M}$, and $\Delta(\mathbf{k})$ is the gap function. For a $p_x + ip_y$ condensate, the gap function transforms under rotations as an $\ell = -1$ angular momentum eigenstate, and for $\mathbf{k} \rightarrow 0$, it behaves as $\Delta(\mathbf{k}) = (k_x - ik_y)\Delta$, where Δ is a constant pairing amplitude.

The BCS ground state has the form

$$|G\rangle = \prod_{\mathbf{k}} (u(\mathbf{k}) + v(\mathbf{k}) \psi^\dagger(\mathbf{k}) \psi^\dagger(-\mathbf{k})) |0\rangle \quad (491)$$

where $|u(\mathbf{k})|^2 + |v(\mathbf{k})|^2 = 1$. The amplitudes $u(\mathbf{k})$ and $v(\mathbf{k})$ satisfy the Bogoliubov-de Gennes equation (BdG)

$$\begin{pmatrix} \xi(\mathbf{k}) & -\Delta^*(\mathbf{k}) \\ -\Delta(\mathbf{k}) & -\xi^*(\mathbf{k}) \end{pmatrix} \begin{pmatrix} u(\mathbf{k}) \\ v(\mathbf{k}) \end{pmatrix} \equiv E(\mathbf{k}) \hat{\mathbf{n}}(\mathbf{k}) \cdot \boldsymbol{\sigma} \begin{pmatrix} u(\mathbf{k}) \\ v(\mathbf{k}) \end{pmatrix} = E(\mathbf{k}) \begin{pmatrix} u(\mathbf{k}) \\ v(\mathbf{k}) \end{pmatrix} \quad (492)$$

where $\xi(\mathbf{k}) = \varepsilon(\mathbf{k}) - \mu$, $\boldsymbol{\sigma} = (\sigma_x, \sigma_y, \sigma_z)$ are the Pauli matrices, and $\hat{\mathbf{n}}(\mathbf{k}) = (-\text{Re}\Delta(\mathbf{k}), \text{Im}\Delta(\mathbf{k}), \xi(\mathbf{k}))$ is a unit vector defined for every $\mathbf{k}$. The eigenvalues $E(\mathbf{k})$ and the eigenvectors $(u(\mathbf{k}), v(\mathbf{k}))$ are

$$E(\mathbf{k}) = \sqrt{\xi^2(\mathbf{k}) + |\Delta(\mathbf{k})|^2}, \quad \frac{v(\mathbf{k})}{u(\mathbf{k})} = -\frac{E(\mathbf{k}) - \xi(\mathbf{k})}{\Delta^*(\mathbf{k})}. \quad (493)$$

The spinor amplitudes are $|u(\mathbf{k})|^2 = \frac{1}{2} \left(1 + \frac{\xi(\mathbf{k})}{E(\mathbf{k})} \right)$ and $|v(\mathbf{k})|^2 = \frac{1}{2} \left(1 - \frac{\xi(\mathbf{k})}{E(\mathbf{k})} \right)$.

In the low momentum limit and in real space, the BdG equations become

$$\begin{aligned} i\partial_t u &= -\mu u + \Delta^* i(\partial_x + i\partial_y)v \\ i\partial_t v &= \mu v + \Delta i(\partial_x - i\partial_y)u \end{aligned} \quad (494)$$

which is just the Dirac equation in 2+1 dimensions, with μ playing the role of the mass, and with the restriction that the spinor (u, v) obeys the Majorana condition

$$(u, v) \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} = \begin{pmatrix} u \\ v \end{pmatrix}. \quad (495)$$

The Majorana condition is obeyed in all superconductors and reflects the fact that in these condensates only the fermion parity $(-1)^{N_F}$ (with N_F being the number of fermions) is conserved while the fermion number N_F is not.

This is a good BCS state in that it is fully gapped and is chiral. Assuming that the pair fields in the p_x and p_y channels are equal, they showed that the BCS ground state $|G\rangle$ has the form

$$|G\rangle \sim \exp\left(\frac{1}{2} \sum_{\mathbf{k}} g(\mathbf{k}) \psi^\dagger(\mathbf{k}) \psi^\dagger(-\mathbf{k})\right) |0\rangle. \quad (496)$$

Projected onto a state with N fermions with real space coordinates $\mathbf{x}_i$, the wave function is a Pfaffian

$$\Psi(\mathbf{x}_1, \dots, \mathbf{x}_N) = \langle \mathbf{x}_1, \dots, \mathbf{x}_N | G \rangle = \text{Pf}(g(\mathbf{x}_i - \mathbf{x}_j)). \quad (497)$$

The long-distance behavior of this wave function depends on whether the chemical potential $\mu > 0$ (this is the weak-pairing or BCS regime) or $\mu < 0$ (which is the strong pairing BEC-like regime). While in the case of an s-wave superconductor these two regimes are smoothly connected by a crossover, in the $p_x + ip_y$ case, they are separated by a quantum phase transition at $\mu = 0$. In the weak pairing regime, the function $g(\mathbf{k})$ has the asymptotic long-distance form, as $\mathbf{k} \rightarrow 0$,

$$g(\mathbf{k}) \simeq -\frac{2\mu}{(k_x + ik_y)\Delta^*} \quad (498)$$

where the pair field behaves as $\Delta(\mathbf{k}) \simeq (k_x - ik_y)\Delta$. In real space (in complex coordinates), the function $g(z)$ becomes

$$g(z) = \left(\frac{i\mu}{\pi\Delta^*}\right) \frac{1}{z} \quad (499)$$

which is the form used in the Pfaffian wave function. On the other hand, in the strong pairing regime, $\mu < 0$, $g(\mathbf{k})$ has the asymptotic behavior

$$g(\mathbf{k}) \simeq -A \frac{(k_x - ik_y)}{a_0^{-2} + \mathbf{k}^2} \quad (500)$$

where A and a_0 are functions of Δ and μ ,

$$A = \frac{2|\mu|M\Delta}{2|\mu| + m|\Delta|^2}, \quad a_0 = \frac{1}{2|\mu|} \sqrt{\frac{2|\mu|}{M} + |\Delta|^2}. \quad (501)$$

In real space, at distances $|\mathbf{x}| \gg a_0$, the Fourier transform of $g(\mathbf{k})$ decays exponentially, and as $a_0 \rightarrow \infty$, $\mu \rightarrow 0$, and the Fourier transform $g(z)$ has the power-law behavior

$$g(z) \simeq \left(\frac{i|\Delta|}{2\pi\Delta^*}\right) \frac{1}{z|z|} \quad (502)$$

This means that $\mu = 0$ is a quantum critical point that separates the weak pairing phase from the strong pairing phase, which have distinct properties.

Read and Green then used a topological argument, originally formulated by Volovik (1988) in the context of superfluid ^3He films. To see this, we notice that the three-component unit vector $\hat{\mathbf{n}}(\mathbf{k})$ takes values on the surface of a sphere S_2 . In addition, since $v(\mathbf{k}) \rightarrow 0$ for $\mathbf{k} \rightarrow \infty$ (and, hence $u(\mathbf{k}) \rightarrow 1$), we can wrap the momentum space $\mathbf{k}$ onto a sphere S_2 . Thus $\hat{\mathbf{n}}(\mathbf{k})$ are smooth functions of $S_2 \mapsto S_2$. such maps are classified into the homotopy classes of $\pi_2(S_2) \simeq \mathbb{Z}$ given in terms of the integer-valued topological invariant

$$Q = \frac{1}{4\pi} \int d^2k \hat{\mathbf{n}}(\mathbf{k}) \cdot \partial_{k_x} \hat{\mathbf{n}}(\mathbf{k}) \times \partial_{k_y} \hat{\mathbf{n}}(\mathbf{k}). \quad (503)$$

In the strong pairing phase $\mu < 0$, and $\xi(\mathbf{k}) > 0$ and $\hat{\mathbf{n}}(\mathbf{k})$ takes values only on the northern hemisphere of the target space S_2 . Such maps can be deformed continuously to the North Pole and, hence, are topologically trivial, $Q = 0$. On the other hand, in the weak pairing phase, $\mu > 0$, $\xi(\mathbf{k})$ takes both positive and negative values. In this phase, $\hat{\mathbf{n}}(\mathbf{k})$ is topologically nontrivial and the topological invariant Q takes nontrivial values ± 1 .

The upshot of this analysis is that, in the weak pairing phase, the paired FQH state is, at this mean field level, a two-dimensional *topological superconductor*. Read and Green (2000) further showed that this pairing state has vortices with an interesting fermionic spectrum. A vortex is a state in which at long distances the (complex) amplitude of the $p_x + ip_y$ condensate behaves as $\Delta \exp(i\varphi)$, where φ is the azimuthal angle, which winds by 2π on a circumference of large radius R . The BdG equation, Eq. (494), has zero mode solutions. In polar coordinates (r, φ) the BdG equation the zero modes satisfy

$$\begin{aligned} \Delta i e^{i\varphi} \left(\partial_r + \frac{i}{r} \partial_\varphi \right) v &= \mu u \\ \Delta i e^{-i\varphi} \left(\partial_r - \frac{i}{r} \partial_\varphi \right) u &= -\mu v \end{aligned} \quad (504)$$

The normalizable zero mode spinor solution is

$$\begin{pmatrix} u(r, \varphi) \\ v(r, \varphi) \end{pmatrix} = \frac{f(r)}{\sqrt{r}} \begin{pmatrix} \frac{1}{\sqrt{i}} e^{i\varphi/2} \\ \frac{1}{\sqrt{-i}} e^{-i\varphi/2} \end{pmatrix} \quad (505)$$

where $f(r)$ is given by

$$f(r) \sim \exp\left(-\int_0^r dr' \frac{\mu(r')}{|\Delta|}\right) \sim \exp(-\mu r/|\Delta|). \quad (506)$$

Under a 2π rotation, this spinor solution is double-valued

$$(u(r, \varphi + 2\pi), v(r, \varphi + 2\pi)) = -(u(r, \varphi), v(r, \varphi)) \quad (507)$$

which follows from the global phase invariance. In fact, in all paired states, topological or not, under a global transformation of the pair field by a phase θ , the (composite) fermion must transform with a phase of $\theta/2$,

$$\Delta(x) \mapsto e^{i\theta} \Delta(x), \quad \psi(x) \mapsto e^{i\theta/2} \psi(x), \quad \psi^\dagger(x) \mapsto e^{-i\theta/2} \psi^\dagger(x). \quad (508)$$

In other words, in a paired state, the fermion is nonlocal to the vortex. Hence, under a 2π phase transformation of the pair field, the fermions must change sign, and the spinor zero mode solution must be double-valued. This means that this state has a branch cut.

The structures of the vortex and the fermion zero mode are closely related to the problem of solitons with fractional charge that we discussed in Section “Fractionally charged solitons.” In fact, Jackiw and Rossi (1981) investigated a closely related problem of a theory of Dirac field in 2+1 dimensions coupled to a charged scalar field through a Yukawa coupling with the form of a Majorana mass. They showed that such a theory admits vortex solutions with fermion zero modes. In a subsequent paper, Weinberg (1981) showed that these zero modes are counted by an index theorem which relates the number of zero modes to the vorticity. More recently, Nishida et al. (2010) showed that the relativistic theory of Jackiw and Rossi in the nonrelativistic approximation reduces to the theory of a $p_x + ip_y$ superconductor.

There is, however, a subtle but profound difference between the fermion zero modes of the one-dimensional fractionally charged solitons and the fermion zero modes of a superconductor. In the case of the 1D solitons, the zero modes can be either occupied or empty rendering a soliton charge of $-e/2$ or $+e/2$. However, in the case of the superconductor, the BdG fermions are charge-neutral since their charge has gone into the condensate. Thus, in a superconductor, fermion number is not conserved, and only the fermion parity is conserved. This means that the field operator associated with the vortex zero mode, which we will denote by γ , must be a self-adjoint operator, $\gamma^\dagger = \gamma$.

Ivanov (2001) showed that this behavior is the origin of the non-Abelian fractional statistics in this system. Indeed, if one considers a configuration with $2n$ vortices, each will carry a Majorana zero mode γ_i . Since these are fermion operators, they satisfy the usual anticommutator algebra, $\{\gamma_i, \gamma_j\} = 2\delta_{ij}$. We can (arbitrarily) group the $2n$ Majorana fermion operators into n pairs. For each pair we can define a complex Dirac operator $\psi_j = (\gamma_{2j} + i\gamma_{2j+1})/2$ (and its adjoint), which satisfies the usual fermionic algebra, $\{\psi_j, \psi_k^\dagger\} = \delta_{jk}$. Each Dirac fermion can be either in an empty state or in an occupied state. Thus a system of $2n$ vortices supports a degenerate Hilbert space of dimension 2^{n-1} , which agrees with the results of Nayak and Wilczek (1996). However, the assignment of Majorana operators to specific pairs is actually arbitrary, which amounts to a particular definition of the branch cuts. Changing the assignment of the operators into pairs is then equivalent to a rearrangement of the cuts. In 2006, Stone and Chung (2006) showed that these vortices obey the braiding and fusion properties of *Ising* anyons. These properties follow from the branch-cut configurations that affect the monodromies of the vortices. It is important to stress that the vortices with zero modes are the non-abelions. Majorana fermions are fermions and, as such, are abelian.

In addition to the Moore-Read Pfaffian state, the CFT approach has led to the formulation of new nontrivial FQH states. Read and Rezayi (1999) proposed a series of so-called cluster states, which generalize the concept of paired states. They investigated a particular type of cluster states in which the Pfaffian factor of the MR state is replaced by a correlator of *parafermion* primary fields of a $\mathbb{Z}_k$ CFT of Zamolodchikov and Fateev (1985). Parafermions were originally introduced by Fradkin and Kadanoff (1980) (see also Alcaraz and Köberle, 1981) as a generalization of the fermions of the 2D Ising model to the $\mathbb{Z}_k$ clock model. In this model, one can define several types of parafermions each consisting of the fusion of a charge operator and a magnetic (disorder) operator. These operators obey an algebra of the type $AB = \exp(ip2\pi/k)BA$, where the integer p depends on the electric and magnetic charges of the

parafermions, which is reminiscent of fractional statistics. In close analogy with the Majorana fermions of the 2D Ising model, $\mathbb{Z}_k$ CFT describes the behavior of these systems their self-dual points.

The $\mathbb{Z}_k$ CFT is actually much richer and has more primary fields than the $\mathbb{Z}_2$ case of the Ising model. As a CFT, the $\mathbb{Z}_k$ theory is the same as the CFT on the coset $SU(2) - k/U(1)$. A coset means that a $U(1)$ sector has been projected out of the spectrum. Here we will focus on a special case of the $\mathbb{Z}_3$ CFT. This CFT has a parafermion primary field, which we will call ψ , and a non-Abelian primary that we will call τ . Read and Rezayi (1999) proposed to replace the Pfaffian factor of the MR state with a correlator of N parafermions of a $\mathbb{Z}_3$ CFT and a Laughlin factor with an exponent of $n + 2/3$. Such states require that the number of electrons N be a multiple of 3. Thus, these states can be viewed as states in which the electrons cluster in groups of 3. They also considered the more general case of the $\mathbb{Z}_k$ CFT in which case N is a multiple of k . The resulting filling fractions are $\nu = k/(mk + 2)$ (with $m \geq 0$). The Read-Rezayi $k = 3$ parafermion state is a leading candidate for the observed FQH plateau at $\nu = 12/5 = 2 + 2/5$ (Pan et al., 2003; Xia et al., 2004) (the competing state being the $2/5$ Jain state). There is strong numerical support for the $12/5$ state being a $\mathbb{Z}_3$ parafermion (Rezayi and Read, 2009).

The quasiholes obtained by inserting the primary fields τ in the correlator of parafermions have interesting properties that stem from their basic fusion rule

$$\tau \star \tau = I + \tau \quad (509)$$

Read and Rezayi (1999) showed that the number of conformal blocks for $3n$ quasiholes, that is, the number of degenerate states, in the parafermion theory is the Fibonacci number F_{3n-2} , where $F_1 = 1, F_2 = 2, F_3 = 3, F_4 = 5$. In general $F_m = F_{m-1} + F_{m-2}$. For $m \rightarrow \infty$, the rate of increase approaches the limit $\lim_{m \rightarrow \infty} F_m/F_{m-1} = (1 + \sqrt{5})/2$, which is known as the Golden Mean. In other words, for large m , the dimension of the Hilbert space increases exponentially as $((1 + \sqrt{5})/2)^m$. Aside from these interesting mathematical curiosities, the significance of this fusion rule is that these states, regarded as “qubits,” define unitary transformations that cover uniformly the Bloch sphere, which is required for universal quantum computation (Freedman et al., 2002a).

At the level of topological quantum field theory, the Moore-Read and Read-Rezayi states are related to the non-Abelian Chern–Simons gauge theory with gauge group $SU(2)$ at Chern–Simons level k . In the more general case of the gauge group, $SU(N)$ on a manifold $\mathcal{M}$ action is given by

$$S_{CS}[A_\mu] = \frac{k}{4\pi} \int_{\mathcal{M}} d^3x \epsilon_{\mu\nu\lambda} \left(A_\mu^\alpha \partial^\nu A_\alpha^\lambda + \frac{2}{3} f_{abc} A_\mu^\alpha A_\alpha^\nu A_\nu^\lambda \right) \quad (510)$$

where $k \in \mathbb{Z}$ is the level, the gauge fields $A^\mu = A^\mu_a t_a$ take values in the algebra of $SU(N)$, with $\{t_a\}$ being the $N^2 - 1$ generators, and f_{abc} are the structure constants of $SU(N)$. The expectation values of Wilson loop operators of this theory compute the Jones polynomials that are topological invariants of knot theory (Witten, 1989). The connection with $SU(2)_k$ Chern–Simons gauge theory has been essential in formulating effective low energy quantum field theories for the non-Abelian states (Fradkin et al., 1998, 1999; Barkeshli and Wen, 2010; Goldman et al., 2019, 2020, 2021).

Edge states and chiral conformal field theory

We will now discuss the edge states of the FQH states. As we saw, the FQH states are incompressible in the bulk and all bulk excitations are gapped. The edge of the region occupied by the fluid (in many cases that edge of the physical sample) is where the bulk gap collapses and hence where the system has low energy excitations.

The role of edges and their nature can be seen already in the simple case of the integer Hall effect treated as a system of free fermions in the lowest Landau level. In this state, all single particle states are occupied, and the bulk ground state wave function is a Slater state that takes the form of the Vandermonde determinant of Eq. (377). The potential that keeps the electrons inside the sample increases monotonously near the edge. As we discussed in Section “Landau levels and the integer Hall effect,” in this region, the electrons experience an electric field E that pushes them into the sample, and in the presence of the perpendicular magnetic field B , the electrons move *along the edge* at the drift velocity $v = c|E|/|B|$. At some spatial location, corresponding to the locus of a single particle Landau state, the potential crosses the Fermi energy and in that region, potential is essentially a linear function of the coordinate and hence of momentum (or angular momentum depending on the gauge that is being used). In other words, the low energy states are one branch of a one-dimensional chiral excitation, such as in the right-moving states of our discussion of the chiral anomaly in Section “Chiral symmetry and chiral symmetry breaking.”

In Section “Quantization of Abelian Chern–Simons gauge theory,” we showed that a Chern–Simons gauge theory on a manifold with a boundary projects onto a chiral CFT on that boundary. In that section we showed that an Abelian Chern–Simons theory $U(1)_m$ integrates to the boundary, the 1+1-dimensional Minkowski spacetime $S^1 \times \mathbb{R}$, as a chiral $U(1)_m$ CFT for a compactified boson with compactification radius $R = 1$ whose action is given by

$$S[\varphi] = \int_{S^1 \times \mathbb{R}} d^2x \frac{1}{4\pi} [\partial_0 \phi \partial_1 \phi - v(\partial_1 \phi)^2] \quad (511)$$

where we rescaled the compactified scalar by a factor of $\sqrt{m}$ to that its compactification radius $R = \sqrt{m}$ as in Section “Fractional quantum hall wave functions and conformal field theory.” The only difference between the theory of Eq. (241) and what we did in Section “Fractional quantum hall wave functions and conformal field theory” is that this theory is in a 1+1-dimensional Minkowski

spacetime $S_1 \times \mathbb{R}$ while before we were in Euclidean spacetime. In the case of the integer quantum Hall effect $\nu = 1$ (and hence $m = 1$) and the (time-ordered) correlator of the vertex operator, $V_1(x, t) = \exp(i\phi(x, t))$ is

$$\langle T \exp(i\phi(x, t)) \exp(-i\phi(0, 0)) \rangle = \frac{1}{x - vt - i\epsilon} \quad (512)$$

which is, indeed, the propagator of a chiral free fermion.

On the other hand, for the Laughlin states at filling fraction $\nu = 1/m$ (and compactification radius $R = \sqrt{m}$), the propagator of the electron $\psi_e \sim \exp(i\sqrt{m}\phi)$ is

$$\langle T \exp(i\sqrt{m}\phi(x, t)) \exp(-i\sqrt{m}\phi(0, 0)) \rangle \sim \frac{1}{(x - vt - i\epsilon)^m} \quad (513)$$

while the propagator of the quasi-hole $\exp\left(\frac{i}{\sqrt{m}}\phi\right)$ is

$$\left\langle T \exp\left(\frac{i}{\sqrt{m}}\phi(x, t)\right) \exp\left(-\frac{i}{\sqrt{m}}\phi(0, 0)\right) \right\rangle \sim \frac{1}{(x - vt - i\epsilon)^{1/m}}. \quad (514)$$

Therefore, the CFT of the edge is the same as the CFT of the ideal wavefunction with the only difference that the former is in Minkowski spacetime while the latter is in Euclidean spacetime.

In this sense, there is a one-to-one correspondence between the bulk and the edge. We can also see how that works by considering a fundamental Wilson arc in the bulk along a path $\gamma(x, y)$ where x and y are at the boundary

$$\langle W[\gamma] \rangle = \langle \exp(i \int_{\gamma(x, y)} dx_\mu \mathcal{A}^\mu) \rangle \equiv \langle \exp\left(\frac{i}{\sqrt{m}}\phi(x)\right) \exp\left(-\frac{i}{\sqrt{m}}\phi(y)\right) \rangle \quad (515)$$

where on the right-hand side we have rescaled the field by $\sqrt{m}$, as before. The scaling dimensions of the electron, the quasi-hole, and the current are $\Delta_e = \frac{m}{2}$, $\Delta_{qh} = \frac{1}{2m}$, and $\Delta_{\text{current}} = 1$. These results will be important shortly.

The same structure applies to the multicomponent Abelian FQH states. The only difference is that in multicomponent FQH states, the edge consists, in general, of a charge field that couples to the electromagnetic field and one or more neutral edge states. An example is the theory of the non-Abelian Pfaffian states at filling fraction $\nu = 1/n$. In this case the edge theory consists of a compactified chiral boson ϕ of radius $R = \sqrt{n}$ and a chiral Majorana (neutral) fermion χ . At a formal level, the Lagrangian for the edge state(s) is a sum of two terms

$$\mathcal{L} = \frac{1}{4\pi} (\partial_x \phi \partial_t \phi - v_c (\partial_x \phi)^2) + \chi i (\partial_t - v_n \partial_x) \chi \quad (516)$$

where v_c and v_n are the velocities of the (charged) compactified chiral scalar ϕ and of the neutral Majorana field χ . Numerically (and experimentally) it is known that the charge mode is (substantially) faster than the neutral mode(s), $v_c > v_n$, and often by significant factors.

A superficial reading of this Lagrangian suggests that these degrees of freedom are decoupled. However this is not correct. Only operators from both sectors, which are local with respect to the electron $\psi_e \sim \chi \exp(i\sqrt{n}\phi)$, are physically allowed. Here an operator is local with respect to the electron means that the operator braids trivially with the electron. This condition restricts the allowed observables. In the case of the fermionic MR state, with $n = 2$, the allowed operators are the non-abelian $\sigma \exp(i\phi/2\sqrt{2})$, where scaling dimension is $\Delta = 1/8$ and electric charge is $Q = 1/4$, the Majorana fermion with scaling dimension $\Delta = 1/2$ and no electric charge $Q = 0$, and the Laughlin quasiparticle with scaling dimension $\Delta = 1/4$ and charge $Q = 1/2$. Its electron operator has scaling dimension $\Delta = 3/2$ and charge $Q = 1$.

CFT has an important defining universal quantity called the central charge, which is closely related to the energy-momentum tensor of the theory (Di Francesco et al., 1997). For pedagogical introductions to CFT, see Affleck (1990) and Cardy (1996) and Chapter 21 of Fradkin (2021). The energy-momentum tensor $T_{\mu\nu}$ is a locally conserved current, $\partial^\mu T_{\mu\nu} = 0$. Its local conservation implies the global conservation of energy and momentum. As such, the energy-momentum tensor is a fundamental observable of any quantum field theory. In a CFT, the energy-momentum tensor is also the generator of local scale and conformal transformations. In the special case of 1+1-dimensional systems, such as the edge states of the FQH fluids, the energy-momentum tensor has special and crucially important properties. In addition to being locally conserved, conformal invariance requires that $T_{\mu\nu}$ must be traceless, $T^\mu_\mu = 0$, since its trace is the generator of dilations. In this case, if the theory is chiral, the energy-momentum tensor has only one (right-moving) component $T = (T_{00} - T_{11})/2$. In complex coordinates of the Euclidean metric, the correlator of the energy momentum tensor $T = T_{zz}$ is (Belavin et al., 1984)

$$\langle T(z)T(w) \rangle = \frac{c/2}{(z - w)^4} \quad (517)$$

where c is a universal quantity known as the central charge of the CFT. In the case of the compactified boson, the central charge is $c = 1$, whereas for a massless Majorana fermion, $c = 1/2$.

The central charge of the CFT enters in many observables of fundamental physical importance. For example, for a 1+1-dimensional system of length L , such as the edge state of an FQH droplet, the ground state energy E_{gnd} for large L has the behavior (Affleck, 1986; Blöte et al., 1986)

$$E_{\text{gnd}} = \varepsilon_0 L - c \frac{\pi \nu}{6L} + O(1/L^2) \quad (518)$$

where ε_0 is the ground state energy density, which is a nonuniversal quantity, c is the central charge of the CFT, and ν is the velocity of the massless modes. The second term in Eq. (518) is known as the Casimir energy. Similarly, the free energy density $f(T)$ of a CFT has the low temperature Stefan–Boltzmann behavior (in one dimension)

$$f(T) = \varepsilon_0 + c \frac{\pi T^2}{6\nu} + O(T^3) \quad (519)$$

where we set the Boltzmann constant to unity. The low-temperature specific heat $c(T)$ is

$$c(T) = c \frac{\pi T}{3\nu} + O(T^2). \quad (520)$$

In a chiral CFT, such as the edge states of the FQH fluids, the central charge enters in the low temperature behavior of the (Hall) thermal conductivity κ_{xy} (Read and Green, 2000)

$$\kappa_{xy} = c \frac{\pi T}{6\hbar}. \quad (521)$$

Much of what is known about FQH states comes from experiments involving their edge states. In a series of exquisite experiments of Granger et al. (2009) measured κ_{xy} in the edge states of a $\nu = 1$ quantum Hall fluid and showed that the heat transport is indeed chiral, that is, the edge state behaves as a heat “diode.” This effect was confirmed in the FQH states by Bid et al. (2010) who, in addition, used this effect to detect the neutral modes in several Jain states at filling fractions $2/3$ and $2/5$ and in the non-Abelian state at $\nu = 5/2$. These experiments are a key confirmation that the edge states of fractional quantum Hall states are indeed chiral Luttinger liquids (CLL).

Point contact tunneling and QH chiral edge states

The simplest experimental probes are quantum point contacts and typically are of two types: inter-edge tunneling inside an FQH liquid or tunneling of electrons into the edge state of a FQH liquid. Since the bulk is gapped, only the edge states participate in these tunneling processes. In the general case we will have two edges and a tunnel process at a point contact. Here the two edges can be either the two edges of the same FQH state, in which case the process happens inside the FQH liquid and involves tunneling of quasiparticles, or the edges of different liquids, in which case this process is external and involves tunneling of electrons. Problems of these types were first investigated by Kane and Fisher (1992), which led to a considerable amount of work on these problems.

Let us consider first the case of tunneling into the edge state of a $\nu = 1/m$ Laughlin state from a FL, which we will take to be a QH fluid in the $\nu = 1$ state. The point contact is at $x = 0$. The total Lagrangian is

$$\mathcal{L} = \mathcal{L}_{\text{edge}} + \mathcal{L}_{\text{FL}} - \Gamma e^{i\omega_0 t} \psi_{e,\text{edge}}^\dagger(0, t) \psi_{e,\text{FL}}(0, t) + \text{h.c.} \quad (522)$$

where $\omega_0 = eV/\hbar$, V is the bias voltage between the two fluids, and Γ is a tunneling matrix element. The local electron spectral density (the density of states) $N(\omega)$ at energy ω is

$$N(\omega) = \text{Im} \lim_{x \rightarrow 0^+} \int_{-\infty}^{\infty} dt G_e(x, t) e^{i\omega t} = \text{const.} |\omega|^{m-1} \quad (523)$$

where $G_e(x, t) = \langle T \psi_e^\dagger(x, t) \psi_e(0, 0) \rangle$ is the electron correlator in the FQH edge, shown in Eq. (512). This result, combined with Fermi’s Golden Rule for a point contact with voltage bias V , predicts a tunneling current from a FL into the chiral Luttinger liquid CLL of the edge state to be (Chamon and Fradkin, 1997)

$$I(V) = 2\pi \frac{e}{\hbar} |\Gamma|^2 \int_{-eV}^0 dE N_{\text{CLL}}(E, T) N_{\text{FL}}(E + eV, T) \propto V^m \quad (524)$$

and a tunneling differential conductance $G(V)$

$$G(V) = \frac{dI}{dV} = 2\pi \frac{e}{\hbar} |\Gamma|^2 N_{\text{FL}}(0) N_{\text{CLL}}(V, T) \propto V^{m-1} \quad (525)$$

which is non-Ohmic and vanishes as $V \rightarrow 0$.

Early experiments by Chang et al. (1996) [reviewed by Chang (2004)], on a geometry that (most likely) had many point contacts, confirmed the predicted CLL behavior, although there were discrepancies in the measured exponents. The behavior seen in more recent experiments by Hashisaka et al. (2021) and Cohen et al. (2022) on a point contact in graphene is consistent with the theoretical predictions of Chamon and Fradkin (1997). Interestingly, these newer class of experiments also show evidence of an analog of Andreev reflection predicted to exist near the strong coupling fixed point of the theory of Sandler et al. (1999) as a consequence of electron fractionalization.

Most experiments are done on a geometry call a Hall bar in which the QH fluid occupies a rectangular region with its length L larger than its width W . In this geometry, there are chiral edge states at opposite sides of the Hall bar propagating in opposite directions. One type of point contact consists in creating a constriction in the quantum Hall fluid by applying a gate, a bias potential on a narrow strip across the Hall bar. This gate repels the electrons in the QH fluid, forcing the opposite edges to approach each other in the proximity of the gate. In the absence of the gate, momentum is conserved on each edge, which forbids tunneling across the Hall bar since the edge states have opposite Fermi momentum. However, the gate breaks translation invariance on both edges and tunneling between them is now allowed. In other words, the gate creates a point contact between the opposite propagating edge states leading to a tunneling process between the edges of the QH liquid. Thus, this is internal tunneling as opposed to the process of tunneling between two different liquids that we discussed above.

The tunneling Lagrangian for this system has the same form as in Eq. (522) except that now the two edges are identical. The theory by Kane and Fisher shows that in the fractional case, the most relevant process is the tunneling of FQH quasiparticles. The Fermi Golden Rule argument used in Eq. (525) to compute the differential conductance also applies in the present case except that now the two densities of states are the densities of states of the (Laughlin) quasiparticles (instead of electrons). The local quasiparticle density of states is $N_{qp}(\omega) \sim |\omega|^{\frac{1}{m}-1}$. Then, the differential tunneling conductance $G(V)$ in this case is

$$G(V) \sim V^{2(\frac{1}{m}-1)}. \quad (526)$$

This behavior is also non-Ohmic but, unlike the case of electron tunneling of Eq. (522), the differential tunneling conductance now *diverges* as $V \rightarrow 0$. This behavior means that the $\Gamma \rightarrow 0$ fixed point is *unstable* and that the point contact flow to a *strong coupling fixed point* at $\Gamma \rightarrow \infty$. Early experiments by Milliken et al. (1996) showed indications of CLL behavior. The predicted behavior was confirmed in the experiments of Roddaro et al. (2004a, b).

In the RG language, we can define a dimensionless tunneling amplitude g by $\Gamma = a^{\Delta-1}g$, where Δ is the scaling dimension of the tunneling operator and a is a UV cutoff. The “tree-level” beta function is readily found to be

$$\beta(g) = a \frac{\partial g}{\partial a} = (1 - \Delta) g + O(g^2) \quad (527)$$

which shows that if the scaling dimension of the operator of the tunneling particle is $\Delta < 1$, then this tunneling process is relevant, while $\Delta > 1$ is irrelevant.

Kane and Fisher argued that there should be a crossover from the IR unstable weak-coupling fixed point governed by quasiparticle tunneling to an IR stable strong coupling fixed point governed by electron tunneling. This crossover is reminiscent of the crossover in quantum impurity problems such as the Kondo problem of a magnetic impurity in a metal (Anderson et al., 1970; Wilson, 1975; Andrei, 1980; Wiegmann, 1980; Read and Newns, 1983). The main difference is that the impurity coupling is marginal and the crossover scale, the Kondo temperature T_K , which is related to the coupling constant g as $T_K \sim \exp(-1/g)$, while in the FQH constriction, the crossover scale is $T_K(g) \sim g^{1/(1-\Delta)}$. Kane and Fisher argued that this crossover can be viewed as a process that interpolated between an FQH fluid with a weak constriction to a regime in which the Hall bar splits into two pieces with weak electron tunneling between them.

It turns out that, after some manipulations, the model of the constriction can be mapped into a one-dimensional compactified boson φ on a semi-infinite line, $x \geq 0$, with a vertex operator acting on the boundary. The action of this system, known as boundary sine-Gordon, is

$$S = \frac{1}{8\pi} \int_{-\infty}^{\infty} dt \int_0^{\infty} dx (\partial_\mu \varphi)^2 + \Gamma_{qp} \int_{-\infty}^{\infty} dt \cos\left(\sqrt{\frac{v}{2}} \varphi(0, t)\right). \quad (528)$$

This theory has two fixed points: (a) the IR unstable fixed point at $\Gamma_{qp} = 0$ where the field Neumann boundary conditions at $x = 0$, $\partial_x \varphi = 0$, and (b) an IR stable fixed point at $\Gamma_{qp} \rightarrow \infty$ where the field has Dirichlet boundary conditions, $\varphi = 2\pi\sqrt{2/v} n$ (with $n \in \mathbb{Z}$). It turns out that this is an integrable field theory. Fendley et al. (1995b) used the thermodynamic Bethe Ansatz to calculate the differential tunneling conductance for the Laughlin state at $\nu = 1/3$ as a function of voltage V and temperature T and obtained the full weak to strong crossover RG flow. Detailed predictions of this theory have been verified experimentally by the work of Roddaro et al. (2004a, b). Point-contact experiments were performed in the more challenging $\nu = 5/2$ FQH state by Miller et al. (2007) and Radu et al. (2008). They found that the MR state is the one that best fits their experimental results.

Experimental evidence of fractional charge

The charge of a quasiparticle can, in principle, be found directly by measuring the noise of a weak current. This process is known as shot noise. In the case of the constriction, the quasiparticle current operator is $I_{qp} = 2ev\Gamma_{qp} \sin\left(\sqrt{v/2}\phi + \omega_0^* t\right)$, where $\omega_0^* = evV/\hbar$. The noise spectrum, $S(\omega)$, of the tunneling current I_{qp} is (Kane and Fisher, 1994)

$$S(\omega) = \int_{-\infty}^{\infty} dt \langle \{I_{qp}(t), I_{qp}(0)\} \rangle e^{i\omega t}. \quad (529)$$

Using the expression of the quasiparticle correlator of Eq. (514), one readily finds that, to leading order in Γ_{qp} , the noise spectrum is

$$S(\omega) = ev \langle I_{qp} \rangle \left[\left(1 - \frac{\omega}{\omega_0^*}\right)^{2\nu-1} + \left(1 + \frac{\omega}{\omega_0^*}\right)^{2\nu-1} \right]. \quad (530)$$

In the limit of zero frequency, the noise spectrum takes the shot noise form

$$\lim_{\omega \rightarrow 0} S(\omega) = 2e^* \langle I_{qp} \rangle \quad (531)$$

where the expectation value of the tunneling current is

$$\langle I_{qp} \rangle = \frac{2\pi}{\Gamma(2\nu)} e\nu |\Gamma_{qp}|^2 \omega_0^{*2\nu-1}. \quad (532)$$

Chamon et al. (1996) calculated the exact noise spectrum for the case of a $\nu = 1/2$ bosonic FQH state and were able to investigate the crossover as well, and Fendley et al. (1995a) used the Bethe Ansatz to construct a soliton basis to compute the DC shot noise.

These theoretical predictions were tested in tour-de-force experiments by de Picciotto et al. (1997) and by Saminadayar et al. (1997) who were able to measure the fractional charge of $e/3$ in the $\nu = 1/3$ state and, with some caveats, $e/5$ in the $\nu = 2/5$ state. Subsequent experiments by Dolev et al. (2008) went on to measure the charge from noise experiments in the non-Abelian state at $\nu = 5/2$ and obtained results consistent with $e^* = e/4$ as predicted by theory. A separate experiment by Venkatachalam et al. (2011) used a local electrometer device to measure the electric charge in localized quasiparticles in puddles of the 2DEG at filling fractions $\nu = 5/2$ and $\nu = 7/3$. A statistical analysis of the data showed that the quasiparticle charges are consistent with the theoretical predictions of $e^* = e/4$ for $\nu = 5/2$ and $e^* = e/3$ for $\nu = 7/3$.

Quantum interferometers and fractional statistics

We will now consider experiments on Hall bars with two quantum point contacts created by two narrow gates transversal to the bar and separated at some distance d from each other. Quantum devices of this type are Fabry-Pérot quantum interferometers. The way they operate is as follows: A current is injected in the bottom edge. At the first quantum point contact (QPC), part of the current I_1 tunnels to the opposite edge and the other part I_2 goes on and tunnels at the second QPC. The FQH fluid is assumed to occupy uniformly the region between the two QPCs. There is some magnetic flux Φ in that region, which also contains a number of localized vortices (quasiparticles). When both currents rejoin at the top edge, they interfere and the interference has information on the charge of the particles that tunnels through the Aharonov-Bohm effect with the flux Φ . The interference also has information on the fractional statistics of the quasiparticles that tunneled through their braiding with the static vortices. Chamon, Freed, Kivelson, Sondhi, and Wen proposed a setup of this type to measure the fractional statistics of the quasiparticles for the Abelian states (Chamon et al., 1997). They showed that the total current $I_t = I_1 + I_2$ is given by

$$I_t = e^* |\Gamma_{\text{eff}}|^2 \frac{2\pi}{\Gamma(2\nu)} |\omega_0|^{2\nu-1} \text{sign}(\omega_0^*) \quad (533)$$

where Γ_{eff} is given by

$$|\Gamma_{\text{eff}}|^2 = |\Gamma_1|^2 + |\Gamma_2|^2 + (\Gamma_1 \Gamma_2^* + \Gamma_1^* \Gamma_2) F_\nu \left(\frac{\omega_0^* d}{v} \right). \quad (534)$$

Here Γ_1 and Γ_2 are the tunneling amplitudes at the two QPCs, $\nu = 1/m$ is the filling fraction, v is the velocity of the edge modes, d is the distance between the two QPCs and

$$F_\nu(x) = \sqrt{\pi} \frac{\Gamma(2\nu)}{\Gamma(\nu)} \frac{J_{\nu-1/2}(x)}{(2x)^{\nu-1/2}} \quad (535)$$

where $\Gamma(z)$ is the Euler Gamma function and $J_{\nu-1/2}(z)$ is the Bessel function of the first kind. In the presence of N_q localized quasiparticles in the area between the two QPCs, the contribution of the phases of the tunneling matrix elements gets shifted to

$$\Gamma_1^* \Gamma_2 = \bar{\Gamma}_1 \bar{\Gamma}_2 \exp \left[-2\pi i \left(\nu \frac{\Phi}{\phi_0} - \nu N_q \right) \right] \quad (536)$$

where ϕ_0 is the flux quantum. In Eq. (536), the first term in the phase shift is the Aharonov-Bohm effect of the tunneling quasiparticles while the second term in the phase shift $2\pi\nu N_q$ is the contribution of the fractional statistics of the tunneling quasiparticle as its worldline braids with the N_q localized quasiparticles. This means that there is an interference contribution to the tunneling current (and also to the transmitted current), which is sensitive to both the charge and the fractional statistics of the quasiparticles. This is this effect that is being measured in experiments.

Early attempts at doing this experiment were made by Camino et al. (2005) but were difficult to interpret partly due to subtle reasons related to the difficulty in controlling the actual area of the region comprised between the two QPCs (Halperin et al., 2011). Recent theoretical work by Halperin et al. (2011) showed that the size of the 2DEG in the region comprised by the interferometer plays an important role in the interpretation of these experiments. Thus, if the 2DEG in the region between the two constrictions is small, the device is in a Coulomb blockade regime. A properly working interferometer requires that the interferometer be large enough (and the 2DEG be uniform enough) not to be in this regime. These authors also provided a tell-tale pattern of the oscillations that reveal the detection of fractional statistics. Technical advances in the fabrication and design of these quantum

interferometers led in 2020 to the first successful measurement of the fractional statistics of the quasiholes of the Laughlin state at $\nu = 1/3$ (and also at the Jain state at $\nu = 2/5$) by Nakamura et al. (2020).

The non-Abelian case is more subtle both theoretically and experimentally. The theory of the Abelian interferometer of Chamon et al. (1997) was generalized to the non-Abelian FQH states by Fradkin et al. (1998). The structure of the interferometer is the same as in the Abelian case but the interference effects are different. In addition, in the case of the MR state, aside from the non-Abelian quasiparticle $\sigma \sim \chi \exp(i\phi/2\sqrt{2})$ has charge $e/4$ and non-Abelian fractional statistics, the MR state has two more Abelian anyons, the charge neutral Majorana fermion χ and the charge $e/2$ Laughlin quasiparticle. The number of anyons and their properties are very different in different non-Abelian FQH states.

Ignoring for now the existence of more quasiparticles, let us focus now on the fundamental anyon that is nonabelian. Fradkin et al. (1998) considered a non-Abelian quasihole that is injected to the bottom edge, tunneled at the first QPC, and arrived at the left end of the top edge in state $|\psi\rangle$. If a second such quasiparticle is now injected but now tunnels to the top edge at the second QPC, arriving at the left end of the top edge in the state $e^{i\alpha} B_{N_q} |\psi\rangle$, where α is the Aharonov–Bohm phase determined by the flux Φ piercing the interferometer and B_{N_q} is the braiding operator of the second quasiparticle that is circling around the N_q localized quasiparticles in the interferometer. Then the tunneling conductance measured at the left exit of the top edge has an interference contribution

$$\sigma_{xx} \propto |\Gamma_1|^2 + |\Gamma_2|^2 + \text{Re}[\Gamma_1^* \Gamma_2 e^{i\alpha} \langle \psi | B_{N_q} | \psi \rangle]. \quad (537)$$

The matrix element $\langle \psi | B_{N_q} | \psi \rangle$ is given in terms of the expectation value of the Wilson loop operators of the tunneling quasiparticles braided with the Wilson loops of the N_q localized quasiparticles in the area of the interferometer. In 1989, Witten (1989) showed that this expectation value, which is computed in the non-Abelian Chern–Simons gauge theory, is equal to a topological invariant of the braid known as the Jones polynomial $V_{N_q}(e^{1\pi/4})$. Fradkin et al. (1998) showed that the Verlinde algebra yields a general algorithm for the computation of this matrix element. Therefore, the oscillatory component of the tunneling current (and of the conductance) measures a topological invariant!

However, in the particular case of the MR states, the non-Abelian gauge theory associated with these states is the $SU(2)_2$ Chern–Simons gauge theory. In this case, an explicit calculation Bonderson et al. (2006) and by Stern and Halperin (2006) leads to the result

$$\begin{aligned} \sigma_{xx} &\propto |\Gamma_1|^2 + |\Gamma_2|^2, & \text{for } N_q \text{ odd} \\ \sigma_{xx} &\propto |\Gamma_1|^2 + |\Gamma_2|^2 + 2 |\Gamma_1| |\Gamma_2| (-1)^{N_\psi} \cos\left(\alpha + \arg\left(\frac{\Gamma_2}{\Gamma_1}\right) + \frac{\pi}{4} N_q\right), & \text{for } N_q \text{ even} \end{aligned} \quad (538)$$

Here, $N_\psi = 1$ when the N_q quasiparticles fuse into the state ψ and $N_\psi = 0$ otherwise. The interference effect is absent for N_q odd since an odd number of σ quasiparticles cannot fuse into the identity state I . This simple even-odd effect is special for $SU(1)_2$. In the general case and, in particular in the $SU(2)_3$ case which applies to the $k = 3$ Read–Rezayi (“Fibonacci”) state, the expressions are more complex.

At any rate, even in the MR state the situation is more complicated for two reasons. One is that the charge $e/2$ Abelian Laughlin quasiparticle is always able to tunnel thus spoiling the even-odd effect. The other complication is that the non-Abelian FQH occurs in the $N = 1$ Landau level and the edge states of the non-Abelian FQH state are surrounded by an Abelian $\nu = 2$ state, which makes accessing the interesting edge states more difficult. Robert Willett has pioneered the fabrication and operation of the interferometer for the non-Abelian state at $\nu = 5/2$ (Willett et al., 2009, 2013, 2023). With some significant caveats, these experiments provide solid evidence of non-Abelian braiding, although more work remains to be done on this system.

A variant of the Fabry–Perot interferometer is the Mach–Zehnder well known from quantum optics. Much like the Fabry–Pérot interferometer, this setup has a source and a drain and two “beam splitters.” However, many features of the Fabry–Pérot interferometer which make its operation complex, such as the role of Coulomb interactions and the control of the area of the interferometer, do not play an essential role in the Mach–Zehnder system. In a recent paper, Kundu et al. (2023) report experiments in an electronic Mach–Zehnder interferometer, developed originally by Ji et al. (2003), done in fractional quantum Hall states at $\nu = 1/3$ and $\nu = 2/5$, and found values of the fractional statistics consistent with theoretical predictions.

Quantum Mechanics predicts that in collision experiments of identical particles bosons tend to have enhanced correlations localized in space, effect known as “bunching” while fermions exclude each other, due to the exclusion principle, an effect known as “anti-bunching.” The bunching effect of photons was first confirmed by the celebrated experiments of Hanbury Brown and Twiss (1956). In 2003, Vishveshwara proposed a collider-type setup for anyons in a quantum Hall bar with a “beam” of anyons created by two sources colliding at a “beam splitter,” and detected at two sinks (Vishveshwara, 2003). In that setup, fractional statistics is manifest in the cross correlations of the currents detected at the two sinks. Such correlations are present in the noise (quantum fluctuations) of the detected currents. There were several subsequent proposals for detecting the role of fractional statistics in current noise, for example in quantum point contacts at a tri-junction (Kim et al., 2005). Further theoretical work on the collider setup by Vishveshwara and Cooper (2010) and by Rosenow et al. (2016) refined and clarified the role of fractional statistics in anyon collider setups. An experiment by Bartolomei et al. (2020) confirmed the theoretical prediction that, compared to fermions, anyons of a fractional quantum Hall state with filling fraction $\nu = 1/3$ have a bunching tendency (compared to fermions) at a beam splitter consistent with the predicted fractional statistics $\pi/3$.

Particle-vortex dualities in 2+1 dimensions

Electromagnetic duality

The oldest form of duality in Physics is, perhaps, Dirac's observation that in the absence of electric charges and currents, Maxwell's equations are invariant under the exchange of electric and magnetic fields, $E \rightarrow B$ and $B \rightarrow -E$ (Dirac, 1931). This observation led him to conjecture the existence of magnetic monopoles. In a relativistic invariant formulation, Maxwell's equations in free space can be expressed in terms of the electromagnetic field tensor $F_{\mu\nu}$ and the dual field tensor $F_{\mu\nu}^*$

$$\partial^\mu F_{\mu\nu} = 0, \quad \partial^\mu F_{\mu\nu}^* = 0 \quad (539)$$

where $F_{\mu\nu}^* = \frac{1}{2} \epsilon_{\mu\nu\lambda\rho} F^{\lambda\rho}$, and where $\epsilon_{\mu\nu\lambda\rho}$ is the fourth-rank antisymmetric Levi-Civita tensor. The first Maxwell equation in Eq. (539) is just the wave equation in free Minkowski spacetime. The second equation in Eq. (539) is known as the Bianchi identity. The Bianchi identity is a *constraint* that implies that there are no magnetic monopoles and that the second rank antisymmetric field strength tensor can be expressed in terms of the vector potential A_μ as $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$.

This is an example of what in differential geometry is called *Hodge duality*, which relates a vector or more generally a tensor field to its Hodge dual. In general in D dimensions, the Hodge dual of a (fully antisymmetric) tensor of rank p is an antisymmetric tensor of rank $D - p$. When contracted with the oriented infinitesimal element of a p -dimensional hypersurface, $dx_1 \wedge dx_2 \wedge \dots \wedge dx_p$, an antisymmetric tensor of rank p , $F_{\mu_1 \mu_2 \dots \mu_p}$, defines a p -differential form, called a p -form. Differential forms embody the physically intuitive notions of circulation of a vector field, flux of a second rank tensor, etc. We will see below that duality transformations are closely related to these geometric notions of duality.

Particle-vortex duality in 2+1 dimensions

In this section, we will extend the particle-vortex duality discussed in 2D in Section "Vortices in two dimensions" (see Eq. 75) to 3D. In the field theory interpretation, 2D is a 1+1-dimensional Minkowski spacetime and the XY model is a representation of a complex scalar field of unit modulus. In the duality, the particles are the particle-like excitations of the complex scalar field. The high temperature phase of the XY model is viewed as a partition function of a set of oriented loops that carry charge. the loops are the worldlines of the particles of the XY model.

The 3D XY model

This picture can be seen as follows: Consider an XY model on a D -dimensional hypercubic lattice whose sites are labeled by $\{r\}$. At each site, there is a periodic variable $\theta(r) \in [0, 2\pi)$. The partition function is

$$Z_{XY} = \prod_r \int_0^{2\pi} \frac{d\theta(r)}{2\pi} \exp \left(\frac{1}{T} \sum_r \sum_{j=1, \dots, D} (\cos \Delta_j \theta(r)) \right) \quad (540)$$

where $\Delta_j \theta(r) = \theta(r + e_j) - \theta(r)$, with $j = 1, \dots, D$, is the lattice difference, and T is the temperature (in the classical statistical mechanical picture). Since the interaction on each link is a periodic function of the phase difference $\Delta_j \theta(r)$, we can expand the Gibbs weight (for each link!) in a Fourier series or, what is the same, in the integer-valued representations of the group $U(1)$ (which is the global symmetry of the XY model) to obtain

$$Z_{XY} = \prod_r \int_0^{2\pi} \frac{d\theta(r)}{2\pi} \sum_{\ell_j(r)=-\infty}^{\infty} \exp \left(-\sum_{r,j} \frac{T}{2} \ell_j^2(r) + i \sum_r \theta(r) \Delta_j \ell_j(r) \right) \quad (541)$$

where we used a Gaussian approximation for the modified Bessel function $I_n(z)$, and $\Delta_j \ell_j(r) = \sum_{j=1}^D (\ell_j(r) - \ell_j(r - e_j))$ (where e_j is the lattice unit vector along the direction j) denotes the lattice divergence. Integrating out the phase variables $\theta(r)$, we obtain

$$Z_{XY} = \prod_r \sum_{\ell_j(r)=-\infty}^{\infty} \prod_r \delta(\Delta_j \ell_j(r)) \exp \left(-\sum_r \sum_{j=1}^D \frac{T}{2} \ell_j^2(r) \right). \quad (542)$$

Therefore, the partition function is given by a sum over loops of conserved currents $\ell_j(r)$ defined on the links of the lattice, with a weight on each link $\propto \exp(-\ell_j^2/2\beta)$. These loops are the (lattice) worldlines of the particles of the complex scalar field. In the phase where this representation is convergent, the complex scalar field is massive, the XY model is gapped, and these particles have short-range interactions. This picture is true in all dimensions, 3D included.

On the other hand, in 2D, the vortices are point-like events in Euclidean spacetime, which interact with each other through long-range, logarithmic, interactions. In the field theory language, in 2D the point-like vortices are *instantons*, which govern the low temperature phase of the XY model. In spacetime dimensions $D > 2$, the vortices become extended objects: vortex loops (or strings) in 3D, closed vortex surfaces in 4D, etc. In 3D, the vortex loops are magnetic flux tubes, which interact with each other through a Biot-Savart-type interaction, namely bits of vortices interact with each other with a 3D Coulomb interaction much in the same way as with loops of current in magnetostatics,

$$Z_{3D\ XY} = \sum_{\{m_j(\tilde{r})\}} \prod_{\tilde{r}} \delta(\Delta_j m_j(\tilde{r})) \exp \left(-\frac{2\pi^2}{T} \sum_{\tilde{r}, \tilde{r}'} \sum_{j=1}^3 m_j(\tilde{r}) G_0(\tilde{r} - \tilde{r}') m_j(\tilde{r}') - \alpha \sum_{\tilde{r}, j} m_j^2(\tilde{r}) \right) \quad (543)$$

where $\{\tilde{r}\}$ labels the sites of the dual (cubic) lattice, the variables $m_j(\tilde{r})$ take values on the integers, α is a (short-distance) vortex core energy, and $G_0(\tilde{r} - \tilde{r}')$ is the 3D lattice propagator (Green function), which, at long distances, has the standard form

$$G_0(\mathbf{x} - \mathbf{x}') = \frac{1}{4\pi|\mathbf{x} - \mathbf{x}'|} \quad (544)$$

In Eq. (543), the vortex loops are represented by the integer-valued conserved currents $m_j(\tilde{r})$, which are naturally interpreted as the world lines of magnetic charges.

We could have also reached the same result by following the line of reasoning that we used in Section “Vortices in two dimensions.” Indeed, let $\theta(x)$ be the phase field of a complex scalar field $\phi(x)$ deep in its broken symmetry state where the amplitude of the field $\phi(x)$ can be taken to be approximately fixed. The partition function in this phase reduces to

$$Z[a_\mu] = \int \mathcal{D}\theta \exp \left(-\frac{1}{2g} \int d^3x (\partial_\mu \theta - a_\mu)^2 \right) \quad (545)$$

where g is a coupling constant, which in the XY model is proportional to the temperature. Here, much as in Eq. (70), the gauge field a_μ represents the vortices. Indeed, in 3D, the vorticity is represented by a locally conserved vector field ω_μ

$$\omega_\mu = \epsilon_{\mu\nu\lambda} \partial_\nu a_\lambda = 2\pi \sum_k m_\mu^k \delta(x - x_k) \quad (546)$$

where m_μ^k are the integer-valued vortex (magnetic) currents we used above. As before, the periodic nature of the phase field $\theta(x)$ implies that the vortex currents must be quantized and be integer-valued.

Here too, we can perform a Hubbard–Stratonovich transformation in terms of a vector field b_μ to find a dual theory, which now is

$$Z(a_\mu) = \int \mathcal{D}b_\mu \mathcal{D}\theta \exp \left(-\frac{g}{2} \int d^3x b_\mu^2 - i \int d^3x b_\mu (\partial_\mu \theta - a_\mu) \right). \quad (547)$$

Upon integrating out the phase field θ , which acts as a Lagrange multiplier which imposes the constraint $\partial_\mu b_\mu = 0$. This constraint implies that we can write the field b_μ in terms of a dual gauge field ϑ_μ

$$b_\mu = \epsilon_{\mu\nu\lambda} \partial_\nu \vartheta_\lambda. \quad (548)$$

Therefore, we can rewrite the partition function as

$$Z(a_\mu) = \int \mathcal{D}\vartheta \exp \left(-\frac{g}{4} \int d^3x f_{\mu\nu}^2 + i \int d^3x \omega_\mu \vartheta_\mu \right) \quad (549)$$

where $f_{\mu\nu} = \partial_\mu \vartheta_\nu - \partial_\nu \vartheta_\mu$ is the field strength of the dual gauge field ϑ_μ . Notice that the vortex current ω_μ is minimally coupled to the dual gauge field ϑ_μ . If we now integrate out the gauge field ϑ_μ we obtain an expression for the weight in the path integral for a configuration of vortices m_μ^k , which is identical to the result of Eq. (543).

What we have shown above is that in 3D, the Goldstone phase of a complex scalar field with coupling constant g is the dual of a Maxwell gauge theory with coupling constant $1/g$. Moreover, the periodicity of the phase field implies that the dual gauge field ϑ_μ is compact in the sense that its fluxes must obey flux quantization. It is straightforward to show that a charge operator $V_n = \exp(in\theta)$ with electric charge n in the scalar field theory is represented in the dual gauge theory by a magnetic monopole of magnetic charge n .

In summary, we showed that the 3D XY model (equivalent to the theory of the complex scalar field) can be written in terms of two different models of loop configurations. We saw that the XY model is a theory of particle (electric) loops in the high-temperature phase and of vortex (magnetic) loops in the low-temperature phase. However the particle loops have short-range interactions while the vortex loops have long-range interactions. Thus, the 3D XY model is not self-dual. In spite of having a representation in terms of vortex loops, the 3D XY model is in reality has a very different behavior than the 2D system. The Kosterlitz–Thouless theory describes the phase transition in terms of a vortex–antivortex unbinding transition upon which the vortices proliferate. In addition, in 2D, the Goldstone phase is actually a line of fixed points; there is never true long-range order but, instead, power-law correlations of the physical observables. In the Kosterlitz–Thouless theory the disordered phase arises the strong fluctuations of the phase field due to the proliferation of vortices while, at the local level, the order parameter still has a finite magnitude. A consequence of this behavior is that the superfluid density has a universal jump at the Kosterlitz–Thouless transition (Nelson and Kosterlitz, 1977).

In contrast in the 3D XY model, the Goldstone phase is a true phase with long-range order. The theory has a continuous phase transition (the thermodynamic superfluid transition) at which the superfluid density vanishes continuously. This means that the phase transition of the 3D XY is better described by the Wilson–Fisher fixed point of a complex scalar field (Wilson and Fisher, 1972; Amit, 1980), rather than by a vortex proliferation picture of the Kosterlitz–Thouless theory (Kosterlitz and Thouless, 1973;

Kosterlitz, 1974). In particular, since this theory does not have magnetic monopoles, the vortex loops cannot proliferate as they do in 2D. Instead, as the phase transition is approached, the vortex loops not only grow large in size but also become fractal-like objects whose effective core size diverges as the transition is approached. In fact, qualitative vortex proliferation arguments readily lead to the incorrect conclusion that the transition should be (strongly) first order (Thomas and Stone, 1978).

In spite of these differences, particle-vortex duality still plays an important role in 3D by relating the 3D XY model to another theory, which is its dual under electromagnetic duality. Here electromagnetic duality is understood as the exchange of the electric worldlines (electric loops) and the magnetic loops (vortex loops) while exchanging strong and weak coupling, $T \leftrightarrow 1/T$, in this case between different theories. This duality was investigated by Peskin (1978), by Thomas and Stone (1978), and by Dasgupta and Halperin (1981).

Scalar QED in 3D

These authors considered a theory of a superconductor represented by a complex scalar field $\varphi(x)$, coupled to a fluctuating electromagnetic (Maxwell) field, also known as the Abelian Higgs model, or scalar electrodynamics (scalar QED) a_μ with $\mu = 1, 2, 3$. The partition function of this theory is

$$Z_{\text{SC}} = \int \mathcal{D}\varphi \mathcal{D}\varphi^* \mathcal{D}a_\mu \exp \left(- \int d^3x \mathcal{L}[\varphi, \varphi^*, a_\mu] \right) \quad (550)$$

where

$$\mathcal{L} = |D_\mu(a)\varphi|^2 + m^2|\varphi|^2 + u|\varphi|^4 + \frac{1}{4e^2}f_{\mu\nu}^2 \quad (551)$$

where the covariant derivative is $D_\mu(a) = \partial_\mu + iq a_\mu$ with the integer q being the charge of the scalar field (in units of the coupling constant e), and $f_{\mu\nu} = \partial_\mu a_\nu - \partial_\nu a_\mu$ is the field strength. This theory is known as (Euclidean) scalar electrodynamics (or the Abelian Higgs model).

The scalar electrodynamics was extensively studied using the perturbative renormalization group within the epsilon expansion (near 4 dimensions), which leads to the conclusion that it has a weakly (fluctuation-induced) first-order phase transition (Coleman, 1973; Halperin et al., 1974). Scalar QED of an N -component scalar field coupled to a Maxwell gauge field has a continuous phase transition with a nontrivial fixed point for $N \geq N_c \simeq 183$ (!) (Moshe and Zinn-Justin, 2003). Since these results rely on perturbation theory (or in the large- N limit), it was long suspected that the physics may be different in $D = 3$. We will see that particle-vortex duality provides the answer to this question (Dasgupta and Halperin, 1981).

We begin by writing the lattice version of Eq. (550), which is obtained by coupling the XY model of Eq. (540) to a dynamical (Euclidean) Maxwell field

$$Z_{\text{SC}} = \prod_{\mathbf{r}} \int_0^{2\pi} \frac{d\theta(\mathbf{r})}{2\pi} \int_{-\infty}^{\infty} \frac{da_\mu(\mathbf{r})}{2\pi} \exp(-S(\theta, a_\mu)) \quad (552)$$

where the action $S(\theta, a_\mu)$ is

$$S(\theta, a_\mu) = -\frac{1}{T} \sum_{\mathbf{r}, \mu} \cos(\Delta_\mu \theta(\mathbf{r}) - q a_\mu(\mathbf{r})) + \frac{1}{4e^2} \sum_{\mathbf{r}, \mu, \nu} (\Delta_\mu a_\nu(\mathbf{r}) - \Delta_\nu a_\mu(\mathbf{r}))^2. \quad (553)$$

In this action we assumed that the Abelian gauge fields do not have monopole configurations.

The partition function of Eq. (550) admits a representation as a sum over loops. We can then use the same line of reasoning that led to Eq. (542) and write the partition function as a sum over loops of the worldlines of the particles (charges) of the complex scalar field

$$\frac{Z_{\text{SC}}}{Z_0^{\text{gauge}}} = \prod_{\mathbf{r}} \sum_{\ell_\mu(\mathbf{r})=-\infty}^{\infty} \delta(\Delta_\mu \ell_\mu(\mathbf{r})) \exp \left(- \sum_{\mathbf{r}, \mu} \frac{T}{2} \ell_\mu^2(\mathbf{r}) \right) \left\langle \exp \left(i q \sum_{\mathbf{r}, \mu} \ell_\mu(\mathbf{r}) a_\mu(\mathbf{r}) \right) \right\rangle_a \quad (554)$$

where $\langle \mathcal{O}[a] \rangle_a$ is the expectation value of the operator $\mathcal{O}[a]$ over the gauge fields a_μ , and Z_0^{gauge} is the partition function of the free gauge fields. After computing this free-field expectation value, we obtain the result

$$\frac{Z_{\text{SC}}}{Z_0^{\text{gauge}}} = \sum_{\{\ell_\mu(\mathbf{r})\}=-\infty}^{\infty} \delta(\Delta_\mu \ell_\mu(\mathbf{r})) \exp \left(- \sum_{\mathbf{r}, \mu} \frac{T}{2} \ell_\mu^2(\mathbf{r}) - \frac{q^2 e^2}{2} \sum_{\mathbf{r}, \mu} \sum_{\mathbf{r}', \nu} \ell_\mu(\mathbf{r}) G_{\mu\nu}(\mathbf{r} - \mathbf{r}') \ell_\nu(\mathbf{r}') \right) \quad (555)$$

where

$$G_{\mu\nu}(\mathbf{r} - \mathbf{r}') = \langle a_\mu(\mathbf{r}) a_\nu(\mathbf{r}') \rangle \quad (556)$$

is the Euclidean propagator of the free gauge fields. Since the configurations of the worldlines, the currents represented by $\ell_\mu(\mathbf{r})$ are conserved and satisfy the local constraint $\Delta_\mu \ell_\mu = 0$, the second term in the exponent of Eq. (555) is gauge invariant. Hence, we can use the propagator in the Feynman gauge

$$G_{\mu\nu}(\mathbf{r} - \mathbf{r}') = \delta_{\mu\nu} G_0(\mathbf{r} - \mathbf{r}') \quad (557)$$

where $G_0(\mathbf{r} - \mathbf{r}')$ is the 3D lattice propagator that has the same Coulomb form at long distances already given in Eq. (544).

Therefore we can write the partition function of the scalar QED model (the superconductor) as a sum over worldline loop configurations of the particles of the scalar field in the equivalent form

$$\frac{Z_{\text{SC}}}{Z_0^{\text{gauge}}} = \sum_{\{\ell_\mu(\mathbf{r})\}=-\infty}^{\infty} \delta(\Delta_\mu \ell_\mu(\mathbf{r})) \exp \left(- \sum_{\mathbf{r}, \mu} \frac{T}{2} \ell_\mu^2(\mathbf{r}) - \frac{q^2 e^2}{2} \sum_{\mathbf{r}, \mathbf{r}', \mu} \ell_\mu(\mathbf{r}) G_0(\mathbf{r} - \mathbf{r}') \ell_\mu(\mathbf{r}') \right) \quad (558)$$

which is the same as the partition function of the 3D XY model in the broken symmetry state, given in Eq. (543), with the identification of the particle loops of the Abelian Higgs model with the vortices of the 3D XY model and a relation between the coupling constants. Hence we obtain the duality between the broken symmetry phase of the 3DXY model ("low T") and the symmetric phase of the Abelian Higgs model ("high T")

$$\ell_\mu \leftrightarrow m_\mu, \quad q^2 e^2 \leftrightarrow \frac{2\pi^2}{T}, \quad T \leftrightarrow \alpha \quad (559)$$

where the quantities on the left-hand side of the identifications refer to the 3D Abelian Higgs model and the quantities on the right-hand side to the 3D XY model.

We can now repeat the same analysis but in the broken symmetry of the Abelian Higgs model. In this phase the gauge field a_μ becomes massive by the Higgs mechanism (or, what is the same, by the Meissner effect of the superconductor), and in this phase, the vortex loops m_μ of the complex scalar field have short-range interactions. This phase then is mapped onto the unbroken phase of the 3DXY model with the screened vortex loops of the Abelian Higgs model identified with the particle loops of the 3D XY model, and with the same identifications between the coupling constants of the two theories given in Eq. (559). The identification between the two partition functions implies that the phase transitions must be the same. In other words, the duality implies that the 3D Abelian Higgs model has a continuous phase transition with the same fixed point as that of the complex scalar field in 3D. The only difference is that the phases are reversed and, for this reason, this is sometimes called an "inverted" 3D XY transition (Dasgupta and Halperin, 1981).

The duality mapping

We can summarize these results with the following identification of two Lagrangians (in real time, Minkowski signature) (Seiberg et al., 2016)

$$|\partial_\mu(B)\phi|^2 - m^2|\phi|^2 - u|\phi|^4 \leftrightarrow |\partial_\mu(a)\varphi|^2 + m^2|\varphi|^2 - u|\varphi|^4 - \frac{1}{4e^2} f_{\mu\nu}^2 + \frac{1}{2\pi} \epsilon_{\mu\nu\lambda} a^\mu \partial^\nu B^\lambda. \quad (560)$$

The left-hand side of this equivalence is the Lagrangian of the 3D complex scalar field ϕ and B_μ is a background electromagnetic gauge field. The right-hand side is the Lagrangian of the Abelian Higgs model with a scalar field φ and a $U(1)$ gauge field a_μ . Notice that the mass terms of the two sides are inverted reflecting the reverse order of their two phases. This identification also shows that the current of the scalar field $j_\mu = -\frac{i}{2}(\phi^* \partial_\mu \phi - \phi \partial_\mu \phi^*)$ is identified as

$$j_\mu \leftrightarrow \frac{1}{2\pi} \epsilon_{\mu\nu\lambda} \partial_\nu a_\lambda. \quad (561)$$

The field operator of the complex scalar field creates worldlines (as opposed to loops) of charged particles. In the dual Abelian Higgs theory, this operator is identified with an operator that creates a magnetic monopole of the $U(1)$ gauge field a_μ with unit magnetic charge. It is easy to see that in the broken symmetry phase of the Abelian Higgs model, a monopole–antimonopole pair creation operator decays exponentially with distance due to the flux expulsion effect (the Meissner effect of a superconductor). This means that the monopoles are confined with a linear potential. This is the same behavior of the complex scalar field ϕ in its symmetric phase where the propagator of the complex scalar field decays exponentially with distance. Conversely, in the broken symmetry phase of the complex scalar field theory, the field operator ϕ condenses and its propagator approaches the value $|\langle\phi\rangle|^2$ at long distances. This is the same behavior one readily finds for the monopole operator of the Abelian Higgs model in the symmetric phase.

Bosonization in 2+1 dimensions

The particle-vortex duality that we discussed in Section "Particle-vortex duality in 2+1 dimensions" essentially has been understood since the 1980s. In Section "Bosonization, anomalies, and duality," we discussed in detail the problem of bosonization in 1+1 dimensions, which is a mapping between a massless Dirac fermion and a massless compactified scalar field. As we noted, this mapping is a powerful theoretical tool to investigate nonperturbatively the structure of many theories in 1+1 dimensions of great physical interest. This success has motivated a sustained effort to extend these concepts to higher dimensions where the problem in many ways is more subtle.

Fermi systems in dimensions higher than 1+1 differ from the 1+1-dimensional case in two significant ways. Due to the kinematic restriction of one space dimension, a massless relativistic fermion and a theory of fermions (relativistic or not) at finite density

are mostly equivalent to each other. The reason is quite simple. Consider a free massless Dirac theory in 1+1 dimensions. As we saw, it is equivalent to a theory of two chiral fermions, the right- and left-moving components of the spinor. If we add a chemical potential μ , the right- and left-moving states will be filled up to μ , which is the Fermi energy. While in space dimensions $d > 1$ a finite chemical potential leads to a finite Fermi surface, in $d = 1$ space dimensions the Fermi “surface” is just two points, for the right and left moving fermion modes respectively. The Dirac Hamiltonian at finite chemical potential is

$$\mathcal{H} = \psi^\dagger (-i) \alpha \partial_x \psi - \mu \psi^\dagger \psi. \quad (562)$$

Under a chiral transformation with angle $\theta(x)$, the field operators change as $\psi_R \rightarrow e^{i\theta} \psi_R$ and $\psi_L \rightarrow e^{-i\theta} \psi_L$ and the Hamiltonian becomes

$$\mathcal{H} = \psi^\dagger (-i) \alpha \partial_x \psi - (\mu - \partial_x \theta) \psi^\dagger \psi. \quad (563)$$

Clearly if we choose $\partial_x \theta = \mu$ (or, what is the same, $\theta = \mu x$), the explicit dependence on the chemical potential will be cancelled and the transformed Dirac Hamiltonian will be the same as the Hamiltonian at zero chemical potential. However under this transformation the mass operators transform as $\bar{\psi} \psi \rightarrow \cos(2\mu x) \bar{\psi} \psi$ and $i\bar{\psi} \gamma_5 \psi \rightarrow \sin(2\mu x) i\bar{\psi} \gamma_5 \psi$. In the nonrelativistic context, this change amounts to a modulation of the charge density with wave vector $Q = 2p_F(\mu)$.

In contrast, in space dimensions $d > 1$, the massless Dirac system and a system of fermions at finite density (relativistic or not) are no longer equivalent to each other as the latter system has a Fermi surface (of codimension $d - 1$) while the former system has not. This difference has profound effects on their dynamics: the system of fermions at finite density is, at least in the weak coupling regime, is expected to be a FL (except for an instability to a superconducting state even for infinitesimal attractive interactions) while the massless Dirac theory is stable as all local interactions are irrelevant.

Bosonization of the Dirac theory in 2+1 dimensions

We will now turn to the problem of Bose-Fermi mappings in relativistic systems in 2+1 dimensions. This problem is of great interest in both condensed matter physics and in High Energy Physics.

Bosonization in 2+1 dimensions is a more subtle problem than in 1+1 dimensions that we discussed in Section “Bosonization, anomalies, and duality.” There we saw, in 1+1 dimensions, bosonization consists of a set of operator identities relating two free field theories, a theory of massless Dirac fermions and a compactified massless free scalar field $\phi(x)$. The success of that program is largely based on the fact that both theories are massless (and hence are scale and conformally invariant), on the chiral anomaly, and on the relation between the gauge current of the Dirac theory with the topological current of the compactified boson.

The physics in 2+1 dimensions (and in general) is very different. For instance, instead of the chiral anomaly in 2+1 dimensions theories of relativistic fermions have a parity anomaly, discussed in Section “The parity anomaly.” We will also see that although in 2+1 dimensions there are theories of free massless Dirac fermions and free massless compactified bosons, they are no longer dual to each other. For these and other reasons, it has been difficult to extend the bosonization program to 2+1 dimensions.

One of the first bosonization constructions for a theory of massive (relativistic) Dirac fields was put forth by Polyakov (1988) and Grundberg et al. (1990). For reasons that were no longer relevant, Polyakov considered a theory of CP^1 complex scalar fields (in its unbroken phase) coupled to a $U(1)_1$ Chern–Simons gauge theory. Nevertheless, his main argument, with some corrections associated with the parity anomaly, still holds correct.

Here we will follow the work of Goldman and Fradkin (2018b) and consider instead a theory of a single massive complex field coupled to a $U(1)_1$ Chern–Simons gauge theory whose Lagrangian density is

$$\mathcal{L} = |D_\mu(\mathcal{A}_\mu) \phi|^2 - m^2 |\phi|^2 - \lambda |\phi|^4 + \frac{1}{4\pi} \epsilon_{\mu\nu\lambda} \mathcal{A}^\mu \partial^\nu \mathcal{A}^\lambda. \quad (564)$$

In essence, this theory is a relativistic version of what we did in Section “Composite Boson field theory” where we mapped nonrelativistic fermions to (also nonrelativistic) bosons whereas here the theory is relativistic and we are mapping bosons to fermions. In his work, Polyakov actually considered the problem of the propagator of a free massive scalar field coupled to the Chern–Simons gauge field. In this limit, the propagator $G(x, x')$ is the transition amplitude from x to x' (in Minkowski spacetime). In the case in which $\phi(x)$ is a free massive field, this propagator can be expressed in the form of a Feynman path integral as a sum over all open-oriented paths $\{P_{x,x'}\}$ with endpoints at x and x' which in Euclidean spacetime is

$$G_{\gamma(x,x')} = \sum_{\{P_{x,x'}\}} \exp(-mL(P_{x,x'})) \left\langle \exp \left(i \int_{P_{x,x'}} dz_\mu \mathcal{A}^\mu(z) \right) \right\rangle_{U(1)_1} \quad (565)$$

where the expectation value is over the Chern–Simons gauge fields $\mathcal{A}_\mu$ of Eq. (564).

Let us consider now the partition function of the bosons, which is a sum over all closed paths $\{P\}$, which we will assume to be nonintersecting (which requires a short distance repulsion)

$$Z = \sum_{\{P\}} \exp(-mL(P)) \left\langle \exp \left(i \oint_P dz_\mu \mathcal{A}^\mu(z) \right) \right\rangle_{U(1)_1} \quad (566)$$

The expectation value is given by

$$\left\langle \exp \left(i \int_P dz_\mu \mathcal{A}^\mu(z) \right) \right\rangle_{U(1)_1} = \exp \left(-\frac{1}{2} \oint_P \oint_P dx_\mu dy_\nu \langle \mathcal{A}_\mu(x) \mathcal{A}_\nu(y) \rangle \right) \equiv \exp(i\pi W(P)) \quad (567)$$

where $W(P)$ is the *writhe* of the closed path P . The computation of the writhe requires a regularization. One possible regularization is to thicken the path which is equivalent to including a Maxwell term for the gauge field in the Lagrangian. In general, the writhe of the path P is

$$W(P) = SL(P) - T(P) \quad (568)$$

where $SL(P)$ is an integer-valued topological invariant called the self-linking number and $T(P)$ is the twist (or torsion) of the path. The twist $T(P)$ is a Berry phase, which depends on the coordinates of the space in which the path P is embedded, and it is not a topological invariant.

We will now compute the Berry phase $T(P)$. Let $\hat{e}(s)$ be a unit vector tangent to the path P and where we parametrized the closed path P by a coordinate $s \in [0, L]$. The closed path P is the boundary of a surface Σ we can take to be a disk. We will write the Berry phase by extending $\hat{e}(s)$ smoothly to the interior of Σ as $\hat{e}(s, u)$, where $0 \leq u \leq 1$ and $\hat{e}(s, u=1) = \hat{e}(s)$ and $\hat{e}(s, u=0) = \hat{e}_0 \equiv$ constant. With this definition, the Berry phase is

$$T(P) \equiv W(\hat{e}) = \frac{1}{2\pi} \int_0^L ds \int_0^1 du \hat{e} \cdot \partial_s \hat{e} \times \partial_u \hat{e} \quad (569)$$

which is defined modulo an integer.

In this formulation, in the bosonic theory, the amplitude for a path of length L with tangent vector $\hat{e}(s)$ with endpoints at x and x' is

$$G(x - x') = \int_0^\infty dL \int \mathcal{D} \hat{e}(s) \delta(1 - |\hat{e}|^2) \delta\left(x - x' - \int_0^L ds \hat{e}(s)\right) \exp(-|m|L \pm i\pi W(\hat{e})). \quad (570)$$

In momentum space, we find

$$G(p) = \int_0^\infty dL \int \mathcal{D} \hat{e} \delta(1 - |\hat{e}|^2) \exp(-|m|L \pm i\pi W(\hat{e})) \exp(ip^\mu \int_0^L ds \hat{e}_\mu(s)). \quad (571)$$

By inspection of Eq. (569), we see that this is the same expression that we looked in the theory of the path integral for spin in Section “Path integral for a spin- S degree of freedom.” for spin $S = 1/2$ particle in a magnetic field $b_\mu = \pm 2p_\mu$.

The equation of motion for $\hat{e}$ is

$$\partial_s \hat{e}_\mu = \pm 2\epsilon_{\mu\nu\lambda} \hat{e}^\lambda = i[H, \hat{e}_\mu] \quad (572)$$

where $H = \mp p_\mu \hat{e}^\mu$ is the Hamiltonian. Upon quantization, $\hat{e}_\mu$ satisfies the commutation relations

$$[\hat{e}_\mu, \hat{e}_\nu] = 2i\epsilon_{\mu\nu\lambda} \hat{e}^\lambda. \quad (573)$$

This means that we should make the identification $\hat{e}_\mu \rightarrow \sigma_\mu$ where σ_μ are the three 2×2 Pauli matrices. Up to rescaling of the mass $m \rightarrow M$, upon performing the path integral of Eq. (571), we find that $G(P)$ is the (Euclidean) Dirac propagator (Polyakov, 1988)

$$G(p) = \frac{1}{ip_\mu \sigma^\mu - M}. \quad (574)$$

Using these results, the partition function of Eq. (566) becomes

$$Z_{\text{fermion}} = \det[i\cancel{\partial} - M] = \int \mathcal{D}J \delta(\partial_\mu J^\mu) \exp(-|m|L[J] - i\text{sgn}(M)\pi\Phi[J]) \quad (575)$$

where $\Phi[J] = W[J]$, defined in Eq. (568).

We will return to this construction shortly below when we include the effects of the parity anomaly.

Early attempts at deriving a mapping for a theory of Dirac fermions in 2+1 dimensions were based on their behavior in the presence of gauge fields and the associated parity anomaly, discussed in Section “The parity anomaly.” These early theories are essentially a hydrodynamic description of the Dirac theory deep in the massive phase. With minor differences, the same results were derived independently (and simultaneously) by two groups, Fidel Fradkin and Schaposnik (1994) and Burgess and Quevedo (1994). This approach was reexamined more recently by Chan, Hughes, Ryu, and myself in 2016 in a derivation of a hydrodynamic effective field theory for topological insulators in different dimensions (Chan et al., 2013, 2016). These derivations are similar in spirit to what we discussed in Section “Hydrodynamic effective field theory” for the fractional quantum Hall effect. We will follow the approach of Chan et al. (2013) for the special case of a Chern insulator 2+1 dimensions.

The Dirac theory, in any dimension, is globally gauge invariant. By Noether’s theorem, this means that it has a locally conserved current, $j_\mu = \bar{\psi} \gamma_\mu \psi$ which thus satisfies $\partial_\mu j^\mu = 0$. Here too, this means that we can write $j_\mu = \epsilon_{\mu\nu\lambda} \partial^\nu b^\lambda$, where b_μ is a gauge field.

We expect that the effective action of the gauge field b_μ should be local, gauge invariant and, in this case, relativistic invariant. In 2+1 dimensions, the effective action should break time-reversal invariance and hence it should have a Chern–Simons term.

We will consider the free massive Dirac theory coupled to a background probe gauge field A_μ . The Lagrangian is $\mathcal{L} = \bar{\psi}(i(D) - M)\psi$, where $D_\mu = \partial_\mu + iA_\mu$. As we saw in Section “The parity anomaly,” gauge invariance and locality require that we have an even number of Dirac fermions. Here we will assume that one of the Dirac fermions is massive and acts as a regulator. The partition function

$$Z[A_\mu] = \int \mathcal{D}\bar{\psi} \mathcal{D}\psi \exp(iS_F[\bar{\psi}, \psi, A_\mu]). \quad (576)$$

By definition the expectation value of a product of current operators j_μ can be obtained by functional differentiation of the partition function with respect to A_μ .

The partition function is gauge invariant, that is,

$$Z[A_\mu] = Z[A_\mu + a_\mu] \quad (577)$$

where the vector field a_μ is a pure gauge, $a_\mu = \partial_\mu \phi$ and $f_{\mu\nu} = \partial_\mu a_\nu - \partial_\nu a_\mu = 0$. Hence, a_μ is said to be flat. Therefore, up to a normalization

$$\begin{aligned} Z[A_\mu] &= \int \mathcal{D}[a_\mu]_{\text{pure}} Z[A_\mu + a_\mu] \\ &= \int \mathcal{D}a_\mu \delta(f_{\mu\nu} = 0) Z[A_\mu + a_\mu] \\ &= \int \mathcal{D}a_\mu \mathcal{D}b_\mu Z[A_\mu + a_\mu] \exp\left(-\frac{i}{2} \int d^3x \epsilon^{\mu\nu\lambda} b_\mu f_{\nu\lambda}\right) \end{aligned} \quad (578)$$

where in the last equality we introduced a representation of the delta function and the vector field b_μ plays the role of a Lagrange multiplier field. Using the invariance of the integration measure under $a_\mu \rightarrow a_\mu - A_\mu$ we find

$$Z[A_\mu] = \int \mathcal{D}a_\mu \mathcal{D}b_\mu Z[a_\mu] \exp\left(-\frac{i}{2} \int d^3x \epsilon^{\mu\nu\lambda} b_\mu (f_{\nu\lambda} - F^{\nu\lambda})\right) \quad (579)$$

where $F_{\mu\nu}$ is the field strength of the external field A_μ . From these identities and by differentiation of Eq. (579), it follows that a general expectation value of products of currents is

$$\langle j_\mu(x) j_\nu(y) \dots \rangle = \frac{\delta}{\delta A_\mu(x)} \frac{\delta}{\delta A_\nu(y)} \dots Z[A_\mu] = \langle \epsilon_{\mu\alpha\beta} \partial^\alpha b^\beta \epsilon_{\nu\gamma\delta} \partial^\gamma b^\delta \dots \rangle \quad (580)$$

which means that, at the operator level, we can identify (Fradkin and Schaposnik, 1994)

$$j_\mu(x) \leftrightarrow \epsilon_{\mu\nu\lambda} \partial^\nu b^\lambda. \quad (581)$$

This result is actually general. The only difference is the nature of the field b is different dimensions: in 1+1 is a pseudo-scalar, in 2+1 is a vector (gauge) field, in 3+1 is an antisymmetric (Kalb–Ramond) tensor field, etc.

Returning to the partition function of Eq. (579) we find, using the result of Eq. (324) applied the partition function $Z[a_\mu]$, that $Z[A_\mu]$ is given by

$$Z[A_\mu] = \int \mathcal{D}a_\mu \mathcal{D}b_\mu \exp\left(i \int d^3x \mathcal{L}_{\text{eff}}[a_\mu, b_\mu, A_\mu]\right) \quad (582)$$

where the effective Lagrangian is

$$\mathcal{L}_{\text{eff}} = -\epsilon^{\mu\nu\lambda} b_\mu \partial_\nu a_\lambda + \frac{s}{4\pi} \epsilon^{\mu\nu\lambda} a_\mu \partial_\nu a_\lambda - \frac{1}{4g_{\text{eff}}} f_{\mu\nu} f^{\mu\nu} + A_\mu \epsilon^{\mu\nu\lambda} \partial_\nu b_\lambda + \dots \quad (583)$$

where $f_{\mu\nu} = \partial_\mu a_\nu - \partial_\nu a_\mu$. Here, $s = 1$ in the Chern insulator, $s = 0$ in the trivial insulator and $s = 1/2$ at the quantum critical point, and g_{eff} an effective coupling constant (with dimensions of length⁻¹). Here we included the effects of the parity anomaly. We recognize that the first term of the effective Lagrangian of Eq. (583) is a BF term.

In Chan et al. (2013), a similar result is also derived for a 3+1-dimensional topological insulator. The main differences are that there is no parity anomaly but an axial anomaly and that the Lagrange multiplier field is a Kalb–Ramond field,

$$\mathcal{L}_{\text{eff}}[a_\mu, b_{\mu\nu}, A_\mu] = \epsilon^{\mu\nu\lambda\rho} b_{\mu\nu} \partial_\lambda a_\rho + \frac{\theta}{8\pi^2} \epsilon^{\mu\nu\lambda\rho} \partial_\mu a_\nu \partial_\lambda a_\rho - \frac{1}{4g^2} f_{\mu\nu} f^{\mu\nu} + A_\mu \epsilon^{\mu\nu\lambda\rho} \partial_\nu b_{\lambda\rho} + \dots \quad (584)$$

where $\theta = \pi$ in the topological insulator and $\theta = 0$ in the trivial insulator.

Although these results are correct, they do not give a full bosonization mapping. In particular, these results do not identify a fixed point for the dual bosonic theory and, along with it, a full mapping of the observables. Progress on this problem has only been

achieved in the past few years both in the high energy literature (Giombi et al., 2012; Jain et al., 2013; Aharony et al., 2012b, a; Aharony, 2016; Witten, 2016; Seiberg and Witten, 2016; Karch and Tong, 2016), and in the condensed matter physics literature (Son, 2015; Metlitski and Vishwanath, 2016; Wang and Senthil, 2015; Chen et al., 2018; Mross et al., 2016). Much of that new insight was presented in a 2016 insightful paper by Seiberg et al. (2016). Many of the dualities are actually conjectures supported by strong consistency checks. A derivation of the basic bosonization duality based on loop models was constructed by Goldman and Fradkin (2018b).

The basic conjectured bosonization duality is a mapping of a free Dirac fermion to a gauge complex scalar field with a Chern–Simons term (Aharony, 2016; Seiberg et al., 2016). We can think of the Dirac theory as either being defined entirely in 2+1 dimensions or as being defined at the boundary of a nontrivial 3+1 dimensional topological insulator. In the first scenario we need to take into account the contribution of the fermionic doublers (this is what happens in the case of a lattice theory) or as the Pauli–Villars heavy fermionic regulators. In both cases, the additional heavy degrees of freedom cancel the anomaly of the 2+1-dimensional Dirac fermion, see Section “The parity anomaly.” In the second scenario, there is only one Dirac fermion at the boundary and the bulk θ term cancels the anomaly of the boundary theory, see Section “Theta terms, and domain walls: Anomaly and the Callan–Harvey effect.” With these provisos, the Lagrangian $\mathcal{L}_A$ of the free massive (or massless) Dirac fermion in 2+1 dimensions coupled to the electromagnetic gauge field A_μ is

$$\mathcal{L}_A = \bar{\psi}(i\mathcal{D}(A_\mu) - M)\psi - \frac{1}{8\pi}\epsilon_{\mu\nu\lambda}A^\mu\partial^\nu A^\lambda \quad (585)$$

where M is the Dirac mass. We will call this Theory A. Here $\mathcal{D}_\mu(A) = \gamma^\mu(\partial_\mu - iA_\mu)$ and A_μ is a background (nondynamical) gauge field. The last term in Eq. (585) is the Chern–Simons term with the 1/2-quantized coefficient, the usual short-hand for the η -invariant term of Eq. (342) needed to cancel the parity anomaly.

From the effective field theories we discussed above we know that the fermionic current maps to the curl of a gauge field, see Eq (581). Then, the conjectured bosonic dual is given by the Lagrangian of Eq (564) with an extra term for the (dual) coupling to the electromagnetic gauge field. We will call this Theory B whose Lagrangian $\mathcal{L}_B$ is

$$\mathcal{L}_B = |D_\mu(\mathcal{A}_\mu)\phi|^2 - m^2|\phi|^2 - \lambda|\phi|^4 + \frac{1}{4\pi}\epsilon_{\mu\nu\lambda}\mathcal{A}^\mu\partial^\nu\mathcal{A}^\lambda + \frac{1}{2\pi}\epsilon_{\mu\nu\lambda}A^\mu\partial^\nu\mathcal{A}^\lambda. \quad (586)$$

To check the consistence we first observe that both theories are anomaly free. By functional differentiation of the two partition functions, we check that we get the correct mapping for the fermionic current, $j_\mu \leftrightarrow \epsilon_{\mu\nu\lambda}\partial^\nu\mathcal{A}^\lambda$. This mapping implies that the charge density of Theory A maps onto the gauge field flux of Theory B, which is electromagnetic duality. We see that this bosonization is a relativistic version of flux attachment.

Let us now identify the mapping of the phases of both theories. If the Dirac mass $M < 0$, Theory A describes an anomalous quantum Hall insulator. Integrating out the massive fermions, we find that the effective action for the electromagnetic gauge field A_μ is a $U(1)_1$ Chern–Simons theory. This means that in this phase $\sigma_{xy} = -1/(2\pi)$ (in units in which $e = \hbar = c = 1$). Looking now at Theory B, we see that if $m^2 > 0$, the scalar field is in the unbroken phase, and it is massive. In this phase we set $\phi = 0$ and find that the low energy resulting theory is just a $U(1)_1$ Chern–Simons gauge theory coupled to the curl of the electromagnetic field. Upon integrating out the $\mathcal{A}_\mu$ gauge field, we find that the effective action of A_μ is also a $U(1)_1$ Chern–Simons term, which implies that $\sigma_{xy} = -1/(2\pi)$.

Conversely, for $M > 0$, the effective electromagnetic action of the fermionic theory is a Maxwell term (the Chern–Simons term canceled). This phase is a trivial insulator. Looking now at Theory B, we see that for $m^2 < 0$, this theory is in its Higgs phase where $\langle\phi\rangle \neq 0$ and the gauge field $\mathcal{A}_\mu$ now has a mass term, $\propto \mathcal{A}_\mu^2$. In the low energy limit $\mathcal{A}_\mu \rightarrow 0$, and the Hall conductivity vanishes, consistent to what is expected from Theory A.

On the other hand, for $M = 0$, Theory A is at a quantum critical point with a very simple CFT structure but a nonvanishing Hall conductivity $\sigma_{xy} = 1/(4\pi)$. It is natural to map this CFT to a Wilson–Fisher (WF) fixed point of Theory B. At the WF, one sets the (renormalized!) mass $m_R^2 = 0$ (not the *bare* mass). In the absence of the Chern–Simons gauge field, this WF fixed point in well-understood forms high-quality (five loop!) epsilon expansion calculations (enhanced with Borel resummation) (Zinn-Justin, 2002), and by more recent numerical Conformal Bootstrap methods (Simmons-Duffin, 2017). However, not much is known of the *gauged* version of the CFT of Theory B since it cannot be accessed by either methods. If the mapping to Theory A is correct, it should have a Hall conductivity of $\sigma_{xy} = 1/(4\pi)$. This conjectured value has not yet been confirmed.

Consider now a monopole operator of the gauge field $\mathcal{A}_\mu$ of Theory B. We will denote this operator $\mathcal{M}_{\mathcal{A}}$. The Chern–Simons term is not gauge invariant in a monopole background. To put it differently, it has charge 1 under the Chern–Simons gauge field $\mathcal{A}_\mu$. It also has charge 1 under the electromagnetic field A_μ . Likewise the scalar field ϕ has charge 1 under the Chern–Simons gauge field $\mathcal{A}_\mu$. The operator $\phi^\dagger\mathcal{M}_{\mathcal{A}}$ is gauge-invariant under the Chern–Simons gauge field $\mathcal{A}_\mu$ (i.e., it has charge 0). This composite operator has electromagnetic charge 1 (which it inherited from the monopole). Moreover, it has spin-1/2 required by the Wu–Yang construction (Wu and Yang, 1976). In other words, the operator $\phi^\dagger\mathcal{M}_{\mathcal{A}}$ has the *same* quantum numbers as the Dirac fermion and are identified by this conjecture. Notice, however, that the free massless Dirac field has scaling dimension $\Delta_\psi = 1$ in 2+1 dimensions. The conjecture implies the composite operator $\phi^\dagger\mathcal{M}_{\mathcal{A}}$ should also have scaling dimensions 1 at the (gauged) WF fixed point of Theory B. Many of these conjectures have been verified in non-Abelian versions of Theory A and Theory B: a theory of free massless Dirac fermions coupled to a Chern–Simons gauge theory with gauge group $SU(N)_k$ and a theory of complex scalars coupled to a non-Abelian Chern–Simons gauge theory with gauge group $SU(k)_{N'}$, both in the limits $N \rightarrow \infty$ and $k \rightarrow \infty$ with N/k fixed (Giombi et al., 2012; Jain et al., 2013; Aharony et al., 2012b, a; Aharony, 2016).

The particle-vortex duality discussed in Section “Particle-vortex duality in 2+1 dimensions” combined with the fermion-vortex duality we sketched here provide a web of dualities. These identifications constitute a powerful nonperturbative tool, which has led to many significant developments. For instance, [Goldman and Fradkin \(2018a\)](#) used the web of dualities to explain the experimentally observed self-duality at fractional quantum Hall plateau transitions, which was a long standing puzzle. It has also provided a powerful new tool to derive effective field theories of non-Abelian fractional quantum Hall states ([Goldman et al., 2019](#)) and even to propose novel states with a single (Fibonacci) anyon ([Goldman et al., 2021](#)).

Bosonization of the fermi surface

A form of bosonization has been developed for the case of systems of fermions with a Fermi surface. Dense Fermi systems at sufficiently weak coupling are well described by the Landau theory of the Fermi liquid ([Baym and Pethick, 1991](#); [Abrikosov et al., 1963](#); [Nozières and Pines, 1966](#); [Polchinski, 1993](#); [Shankar, 1994](#)). In this regime, the system of fermions has a collective mode, a bound state of particles and holes, which at long wavelengths is well described by the random phase approximation (RPA) ([Bohm and Pines, 1953](#)). However, in space dimensions $d > 1$, there is no kinematical restriction and quasi-particles and quasi-holes may move in their separate ways. The result is that, in addition to the collective modes, there is a low-energy spectrum of renormalized but essentially free quasi-particles. Because of the existence of this quasi-particle spectrum, the collective modes generally (but not always) decay into particle-hole pairs, resulting in a finite lifetime of the collective modes.

Superficially, the particle-hole collective modes are similar to the scalar field of the bosonized theory in $d = 1$. To an extent it has been possible to “bosonize the Fermi surface” and to treat it as a quantum mechanical object ([Haldane, 1994](#); [Houghton and Marston, 1993](#); [Castro Neto and Fradkin, 1994b, a](#); [Houghton et al., 2000](#); [Delacrétaz et al., 2022](#)). In this approach, one essentially regards each direction normal to the Fermi surface as a one-dimensional chiral fermion, including the current algebra structure, subject to global constraints that cancels the anomalies. This point of view ensures that the total fermion number in the Fermi sea is conserved. Here I will only present a short summary of the main ideas.

As in the one-dimensional case, one defines a filled Fermi sea state $|\text{FS}\rangle$. This is a state of noninteracting fermions filling up all one-particle states up to the Fermi energy E_F . For concreteness, we consider a system in two space dimensions. In this case, neglecting lattice effects, the Fermi surface is a circumference of radius p_F , the Fermi momentum. At fixed fermion number, the excitations are particle-hole pairs. The operator $n_k(\mathbf{q}) = c^\dagger(\mathbf{k} + \frac{\mathbf{q}}{2}) c(\mathbf{k} - \frac{\mathbf{q}}{2})$ creates a particle-hole pair with relative momentum $\mathbf{q}$ with total momentum $\mathbf{k}$. In the low-energy regime, $\mathbf{k}$ is a point on the Fermi surface (with $|\mathbf{k}| = p_F$) and $\mathbf{q}$ is small momentum compared with p_F . In what follows we will label the point $\mathbf{k}$ on the Fermi surface by the angle θ of the arc spanned by $\mathbf{k}$ and an arbitrary origin on the Fermi surface.

We will normal-order the particle-hole creation operator with respect to the filled Fermi sea and define $\delta(\mathbf{q}, \theta) =: n_k(\mathbf{q}) := n_k(\mathbf{q}) - \langle \text{FS} | n_k(\mathbf{q}) | \text{FS} \rangle$. [Haldane \(1994\)](#), [Houghton and Marston \(1993\)](#), [Houghton et al. \(2000\)](#), and [Castro Neto and Fradkin \(1994a, b\)](#) showed that in real space these normal ordered density operators obey the equal-time commutation relations

$$[\delta n(\mathbf{x}, \theta), \delta n(\mathbf{x}', \theta')] = -\frac{1}{2\pi} \mathbf{k}_F(\theta) \cdot \nabla \delta^2(\mathbf{x} - \mathbf{x}') \delta(\theta - \theta') \quad (587)$$

where $\mathbf{k}_F(\theta)$ is a unit vector normal to the Fermi surface at angle θ . This is the algebra of the quantum fluctuations of the Fermi surface. We can further define at each point θ on the Fermi surface a Bose field $\varphi(\mathbf{x}, \theta)$ such that

$$\delta n(\mathbf{x}, \theta) = N(0) \mathbf{v}_F(\theta) \cdot \nabla \varphi(\mathbf{x}, \theta) \quad (588)$$

where $N(0)$ is the density of one-particle states at the Fermi surface and $\mathbf{v}_F(\theta)$ is the Fermi velocity at the location θ . The scalar field $\varphi(\mathbf{x}, \theta)$ is a chiral boson at θ which parametrizes the quantum fluctuations of the Fermi surface. The quantum dynamics of the chiral bosons $\varphi(\mathbf{x}, \theta)$ is governed by the action

$$S = \frac{1}{2} N(0) \int_0^{2\pi} \frac{d\theta}{2\pi} \int d^2x dt \left(-\partial_t \varphi(\mathbf{x}, \theta) \mathbf{v}_F(\theta) \cdot \nabla \varphi(\mathbf{x}, \theta) - (\mathbf{v}_F(\theta) \cdot \nabla \varphi(\mathbf{x}, \theta))^2 \right) \\ + \frac{1}{2} N(0) \int_0^{2\pi} \frac{d\theta}{2\pi} \int_0^{2\pi} \frac{d\theta'}{2\pi} \int d^2x d^2x' dt F(\mathbf{x} - \mathbf{x}'; \theta - \theta') \mathbf{v}_F(\theta) \cdot \nabla \varphi(\mathbf{x}, \theta) \mathbf{v}_F(\theta') \cdot \nabla \varphi(\mathbf{x}, \theta') \quad (589)$$

where $\mathbf{x} = (\mathbf{x}, t)$, and $F(\mathbf{x} - \mathbf{x}'; \theta - \theta')$ are the FL parameters that parametrize the effective forward scattering interactions among the fermion quasiparticles on the Fermi surface ([Baym and Pethick, 1991](#)). The equation of motion predicted by this (quadratic) action is equivalent to the linearized quantum Boltzmann equation familiar from the Landau theory of the Fermi liquid. A nonlinear extension has been introduced recently by [Delacrétaz et al. \(2022\)](#). Recent work on the role of quantum anomalies in dense Fermi systems has yielded new insights on these problems ([Shi et al., 2022](#)).

In the regime, where the Landau theory of the Fermi liquid is expected to work ([Baym and Pethick, 1991](#)), bosonization of the Fermi surface approach has reproduced the previously known results. There remain many open problems in this approach (and others) in the vicinity of quantum phase transitions. In spite of intense research using many different approaches, quantum phase transitions in metallic systems are not yet fully understood beyond perturbation theory ([Hertz, 1976](#); [Millis, 1993](#)). Nonperturbative ideas such as deconfined quantum criticality have been proposed ([Senthil et al., 2004](#)) and significant work has been done using large- N methods ([Fitzpatrick et al., 2013](#); [Metlitski et al., 2015](#)). A particularly important metallic quantum phase transition (and perhaps the simplest) occurs near the Pomeranchuk instability of the FL. A quantum phase transition to an electron nematic

state (Oganesyan et al., 2001) has been predicted and studied within the Hertz-Millis approach. It has also been studied using higher dimensional bosonization (Oganesyan et al., 2001; Lawler et al., 2006; Lawler and Fradkin, 2007). Quantum Monte Carlo simulations by Lederer et al. (2015) have shown that the vicinity of a nematic quantum critical point can trigger a superconducting state. Nematic Fermi fluids have been found in many physical systems of interest ranging from high temperature superconductors (such as cuprates and iron superconductors), to electron gases in large magnetic fields (Kivelson et al., 1998; Fradkin et al., 2010, 2015; Fernandes et al., 2019).

Conclusion

In this chapter, I presented the deep and broad role that Quantum Field Theory has in modern condensed matter physics. In spite of the length of this chapter, I have not done justice to its role in many important areas that I did not cover. In particular, I have not touched on the theory of quantum spin liquids, fractions, and particularly topological phases in three space dimensions, among others. An area in which the ideas and concepts of QFT have a huge impact, both conceptually and as a tool, is in the problem of quantum entanglement in Condensed Matter. The concept of quantum entanglement as applied to condensed matter systems, both in equilibrium and out of equilibrium, is a major area of current research and has become a crucial tool for characterizing systems at quantum criticality as well as topological phases of matter.

Abstract

This chapter reviews the standard theoretical wisdom, based on the Bogoliubov-de Gennes mean-field equations, concerning Majorana fermions in so-called topological superconductors and (Fermi) superfluids, and attempts to provide some intuition concerning their nature. The experimental situation is briefly discussed. At the end some doubts about the standard wisdom are expressed.

SRO	Single-layer strontium ruthenate
TQC	Topological quantum computing

Introduction

The concept of a Majorana fermion (hereafter MF) was originally introduced (Majorana, 1937) in a particle-physics context, by Ettore Majorana in 1937; it is a fermionic quasiparticle which is its own antiparticle. More formally, the field operator $\hat{\psi}(\mathbf{r})$ which creates a MF has the property

$$\hat{\psi}(\mathbf{r}) = \hat{\psi}^\dagger(\mathbf{r}), \quad (1)$$

from which follows (with appropriate normalization conventions) the anticommutation relation (ACR)

$$\{\hat{\psi}(\mathbf{r}), \hat{\psi}(\mathbf{r}')\} = \delta(\mathbf{r} - \mathbf{r}') \quad (2)$$

(instead of the standard fermionic ACR which would have zero on the right-hand side).

How can such a particle arise in condensed matter physics? The standard example is the case of a so-called “topological superconductor” (TS), as described by the standard “mean-field” theory which is a generalization of that developed for a simple Bardeen-Cooper-Schrieffer (BCS) superconductor; for the latter, see e.g., Chapter 5 of Ref. (de Gennes, 1966). Consider a general nonrelativistic Hamiltonian of the form $\widehat{\mathcal{H}}_0 + \hat{V}$, where

$$\widehat{\mathcal{H}}_0 \equiv \frac{\hbar^2}{2m} \int d\mathbf{r} \left\{ \sum_{\alpha} \nabla \hat{\psi}_{\alpha}^{\dagger}(\mathbf{r}) \cdot \nabla \hat{\psi}_{\alpha}(\mathbf{r}) + \sum_{\alpha\beta} U_{\alpha\beta}(\mathbf{r}) \hat{\psi}_{\alpha}^{\dagger}(\mathbf{r}) \hat{\psi}_{\beta}(\mathbf{r}) \right\} \quad (3)$$

$$\hat{V} \equiv \frac{1}{2} \sum_{\alpha\beta\gamma\delta} \iint d\mathbf{r} d\mathbf{r}' V_{\alpha\beta\gamma\delta}(\mathbf{r}, \mathbf{r}') \cdot \hat{\psi}_{\alpha}^{\dagger}(\mathbf{r}) \hat{\psi}_{\beta}^{\dagger}(\mathbf{r}') \hat{\psi}_{\gamma}(\mathbf{r}') \hat{\psi}_{\delta}(\mathbf{r}). \quad (4)$$

Here the suffix $\alpha = \pm 1$ is the spin index, and the quantity $\hat{\psi}_{\alpha}(\mathbf{r})$ and its Hermitian conjugate $\hat{\psi}_{\alpha}^{\dagger}(\mathbf{r})$ are field operators satisfying the standard fermionic ACRs

$$\begin{aligned} \{\hat{\psi}_{\alpha}(\mathbf{r}), \hat{\psi}_{\beta}^{\dagger}(\mathbf{r}')\} &= \delta_{\alpha\beta} \delta(\mathbf{r} - \mathbf{r}'), \\ \{\hat{\psi}_{\alpha}(\mathbf{r}), \hat{\psi}_{\beta}(\mathbf{r}')\} &= 0. \end{aligned} \quad (5)$$

[☆]Change History: July 2022. AJ Leggett updated the chapter.

For the moment, we place no particular constraints on the form of the single-particle potential $U_{\alpha\beta}(\mathbf{r})$ or that of the two-particle interaction $V_{\alpha\beta\gamma\delta}(\mathbf{r}, \mathbf{r}')$. Note that the Hamiltonian (3) is automatically invariant under the global $U(1)$ transformation

$$\hat{\psi}_{\alpha}(\mathbf{r}) \rightarrow e^{i\varphi} \hat{\psi}_{\alpha}(\mathbf{r}), \quad \hat{\psi}_{\alpha}^{\dagger}(\mathbf{r}) \rightarrow e^{-i\varphi} \hat{\psi}_{\alpha}^{\dagger}(\mathbf{r}), \quad (6)$$

where φ is a real position-independent constant. (We could of course introduce a vector potential $\mathbf{A}(\mathbf{r})$ and more general gauge transformations, but for simplicity of presentation I do not do so here).

The essence of the mean-field (mf) theory of superconductivity (de Gennes, 1966) consists in introducing the notion of spontaneous breaking of the $U(1)$ symmetry (hereafter abbreviated SBU(1)S) or equivalently the idea that we are free to describe the system by quantum-mechanical states which are not eigenstates of the total particle number operator

$$\hat{N} \equiv \sum_{\alpha} \int d\mathbf{r} \hat{\psi}_{\alpha}^{\dagger}(\mathbf{r}) \hat{\psi}_{\alpha}(\mathbf{r}). \quad (7)$$

Indeed, in mf theory, the ground state of a superconducting system containing an even number of fermions is (explicitly or implicitly) taken in the form

$$\Psi_{(\text{even})} = \sum_{N=\text{even}} C_N \Psi_N, \quad (8)$$

where the quantities C_N are complex coefficients. As a result of the ansatz (8), the “anomalous averages”, that is, expectation values of the form

$$F_{\alpha\beta}(\mathbf{r}, \mathbf{r}') \equiv \langle \hat{\psi}_{\alpha}(\mathbf{r}) \hat{\psi}_{\beta}(\mathbf{r}') \rangle \quad (9)$$

can legitimately be taken to be nonzero in the ground state (and more generally in the superconducting phase). The quantity $F_{\alpha\beta}(\mathbf{r}, \mathbf{r}')$ may be intuitively regarded (apart from its normalization) as the wave function of the Cooper pairs which form in the superconductor (on this see e.g., Ref. (Leggett, 2006), Chapter 5).

The mf method then proceeds by decoupling the expression for the potential energy operator $\hat{V}$, Eq. (4), by a “generalized Hartree-Fock” approximation, in which not only operators of the form $\hat{\psi}_{\alpha}^{\dagger}(\mathbf{r}) \hat{\psi}_{\beta}(\mathbf{r}')$ but also those of the form $\hat{\psi}_{\alpha}(\mathbf{r}) \hat{\psi}_{\beta}(\mathbf{r}')$ are (partially) replaced by their averages. The resulting form of $\hat{V}$ contains not only the standard Hartree and Fock terms, which for simplicity of presentation I will omit, but also the “pairing” (“mf”) term

$$\hat{V}_{\text{mf}} = \sum_{\alpha\beta} \iint d\mathbf{r} d\mathbf{r}' \left\{ \Delta_{\alpha\beta}(\mathbf{r}, \mathbf{r}') \hat{\psi}_{\alpha}^{\dagger}(\mathbf{r}) \hat{\psi}_{\beta}^{\dagger}(\mathbf{r}') + \text{h.c.} \right\}, \quad (10)$$

where the $\hat{\psi}_{\alpha,\beta}^{\dagger}$ are still operators, but the quantity

$$\Delta_{\alpha\beta}(\mathbf{r}, \mathbf{r}') \equiv \sum_{\gamma\delta} V_{\alpha\beta\gamma\delta}(\mathbf{r}, \mathbf{r}') \langle \hat{\psi}_{\gamma}(\mathbf{r}') \hat{\psi}_{\delta}(\mathbf{r}) \rangle \quad (11)$$

is a c -number; Δ is often regarded as a sort of effective mf. While the general expression (10) looks dauntingly complicated, readers may be familiar with the simpler form it takes in the case of a contact interaction $V_0\delta(\mathbf{r})$ and s -wave pairing:

$$\begin{aligned} \hat{V}_{\text{mf}} &= \int d\mathbf{r} \left\{ \Delta(\mathbf{r}) \hat{\psi}_{\uparrow}^{\dagger}(\mathbf{r}) \hat{\psi}_{\downarrow}^{\dagger}(\mathbf{r}) + \text{h.c.} \right\}, \\ \Delta(\mathbf{r}) &\equiv V_0 \langle \hat{\psi}_{\downarrow}(\mathbf{r}) \hat{\psi}_{\uparrow}(\mathbf{r}) \rangle \end{aligned} \quad (12)$$

Before we proceed further, it is necessary to state one caveat: were we to minimize the sum of $\widehat{\mathcal{H}}_0$ and $\hat{V}_{\text{mf}}$ as it stands, then since there is now no explicit restriction on the total particle number N the expectation value of the latter would likely turn out to be zero or at most very small (certainly this will be so if the potential is too weak to form a two-particle bound state in free space). Thus, we need to add to the single-particle energy $\widehat{\mathcal{H}}_0$ a term $-\mu\hat{N}$. With this correction, and continuing to omit the Hartree and Fock terms (which do not affect subsequent arguments qualitatively) the mf [Bogoliubov-de Gennes (BdG)] Hamiltonian is schematically of the form

$$\begin{aligned} \widehat{\mathcal{H}}_{\text{mf}} &= \sum_{\alpha\beta} \left\{ \int d\mathbf{r} K_{\alpha\beta}(\mathbf{r}) \hat{\psi}_{\alpha}^{\dagger}(\mathbf{r}) \hat{\psi}_{\beta}(\mathbf{r}) \right. \\ &\quad \left. + \frac{1}{2} \iint d\mathbf{r} d\mathbf{r}' \Delta_{\alpha\beta}(\mathbf{r}, \mathbf{r}') \hat{\psi}_{\alpha}^{\dagger}(\mathbf{r}) \hat{\psi}_{\beta}^{\dagger}(\mathbf{r}') + \text{h.c.} \right\} \end{aligned} \quad (13)$$

where the notation $K_{\alpha\beta}(\mathbf{r})$ is introduced in the first term as a shorthand for the quantity

$$\delta_{\alpha\beta} \left(\frac{\hbar^2}{2m} \nabla \hat{\psi}_{\alpha}^{\dagger}(\mathbf{r}) \cdot \nabla \hat{\psi}_{\beta}(\mathbf{r}') - \mu \hat{\psi}_{\alpha}^{\dagger}(\mathbf{r}) \hat{\psi}_{\beta}(\mathbf{r}') \right). \quad (14)$$

The operator $\widehat{\mathcal{H}}_{\text{mf}}$ does not conserve particle number, but does conserve the parity of the latter (i.e., it does not mix states with even and odd parity); note that the occurrence of terms proportional to (the operator) $\hat{\psi}^\dagger \hat{\psi}^\dagger$ leads rather naturally to eigenstates of the form (8).

In principle, we may try to use the mf Hamiltonian (13) for either of two purposes: (1) we could try to determine the form of the even-parity ground state [i.e., of the state vectors $\hat{\psi}_N$ and coefficients C_N in Eq. (8)]. This is possible, but actually quite complicated (see e.g., Appendix A of Ref. (Stone and Chung, 2006)), and in fact we need to proceed via the solution of task (2), namely to determine the *relation* between the even-parity ground state and the simplest (“single-fermion”) odd-parity states. It is the latter problem which is central to the question of MF, so I shall from now on specialize to that.

The “textbook” prescription for creating, from the even-parity ground state ψ_{even} , the simplest odd-parity states goes as follows [for simplicity of notation I omit in the following the spin indices: in reality the quantities $\hat{\psi}(\mathbf{r})$, etc., are spinors in *real* spin space (not “Nambu space,” see below): and the u s and v s are matrices.] We construct an operator of the form

$$\gamma_i^\dagger = \int d\mathbf{r} \left\{ u_i(\mathbf{r}) \hat{\psi}^\dagger(\mathbf{r}) + v_i(\mathbf{r}) \hat{\psi}(\mathbf{r}) \right\} \quad (15)$$

and determine the coefficients $u_i(\mathbf{r})$, $v_i(\mathbf{r})$ by requiring $\gamma_i^\dagger$ to satisfy the eigenvalue equation (with E_i the value of $\widehat{\mathcal{H}}_{\text{mf}}$ relative to the even-parity ground state).

$$\left[\widehat{\mathcal{H}}_{\text{mf}}, \gamma_i^\dagger \right] = E_i \gamma_i^\dagger, \quad (16)$$

so that (with appropriate normalization of u_i and v_i , see below)

$$\mathcal{H}_{\text{mf}} = \sum_i E_i \gamma_i^\dagger \gamma_i + \text{const.} \quad (17)$$

The states $\gamma_i^\dagger |\psi_{\text{even}}\rangle$ are then the simplest (“single-fermion”) odd-parity energy eigenstates of the system, and are said to contain a single “Bogoliubov quasiparticle.”

When written out explicitly in terms of the amplitudes $u(\mathbf{r})$, $v(\mathbf{r})$ Eq. (15) becomes a set of linear equations which can be written *schematically* in the form

$$\begin{pmatrix} \hat{K} & \hat{\Delta} \\ \hat{\Delta} & -K^{**} \end{pmatrix} \begin{pmatrix} u \\ v \end{pmatrix} = E \begin{pmatrix} u \\ v \end{pmatrix} \quad (18)$$

where the matrix elements $\hat{K}$ and $\hat{\Delta}$ are themselves matrices in the (real) spin space, and may also be integral operators in (real) coordinate space, cf. Eq. (13). $\hat{\Delta}$ must be calculated self-consistently according to Eq. (11). In the best-known case of simple BCS pairing, the equations take the possibly more familiar form

$$\begin{aligned} (\widehat{\mathcal{H}}_0 - \mu) u(\mathbf{r}) + \Delta(\mathbf{r}) v(\mathbf{r}) &= E u(\mathbf{r}), \\ \Delta^*(\mathbf{r}) u(\mathbf{r}) - (\widehat{\mathcal{H}}_0 - \mu) v(\mathbf{r}) &= E v(\mathbf{r}), \end{aligned} \quad (19)$$

where $u(\mathbf{r})$, $v(\mathbf{r})$ and $\Delta(\mathbf{r})$ are all simple complex scalars. Equations (18) are called the BdG equations, and have been very widely used over the last 50 years in the theoretical literature on superconductivity, including cases more complicated than simple *s*-wave pairing. It is convenient to normalize the u s and v s so that

$$\int d\mathbf{r} (|u|^2(\mathbf{r}) + |v|^2(\mathbf{r})) = 1, \quad (20)$$

whereupon the γ_i s satisfy the standard fermionic ACRs,

$$\left\{ \gamma_i, \gamma_j^\dagger \right\} = \delta_{ij}, \quad \left\{ \gamma_i, \gamma_j \right\} = 0 \quad (21)$$

thereby justifying Eq. (17).

All the above is standard textbook stuff, but it is important to note a crucial point: in this mf treatment, the fermionic quasiparticles are quantum superpositions of a state corresponding to an extra real fermion [with probability amplitude $u(\mathbf{r})$] and one with an extra (real) hole [with amplitude $v(\mathbf{r})$]; this is usually justified by appealing to SBU(1)S. It is conventional to represent this situation by a spinor in the 2D “Nambu space” corresponding to the particle and the hole degrees of freedom:

$$\gamma_j^\dagger \rightarrow \begin{pmatrix} u_j(\mathbf{r}) \\ v_j(\mathbf{r}) \end{pmatrix} \quad (22)$$

and to regard it (to my mind misleadingly, cf. below) as analogous to the mixing of different bands in an insulator by spin orbit coupling; then by analogy with the standard use of the term “topological insulator” for the latter case when the mixing is topologically nontrivial, in the corresponding case for a superconductor one talks about a “topological superconductor”. In the recent literature, it has become common to refer to both of these cases, in the absence of more sophisticated terms than (14) in the

Hamiltonian, as “noninteracting-electron” problems, although the occurrence of the self-consistency condition (11) makes this phrasing rather misleading.

Before proceeding, we need to note a couple of easily verified properties of the γ_i s:

- (1) $\gamma_i |\hat{\psi}_{\text{even}}\rangle = 0$, $\forall_i$ s.t. $E_i \neq 0$.
- (2) If there exists a formal solution to the BdG equations with some positive energy E_i , then by interchanging $u(\mathbf{r})$ and $v(\mathbf{r})$ (and appropriate attention to signs and spin suffixes) we can always construct a solution with negative energy $-E_i$. These “negative-energy” solutions are often regarded (in my opinion misleadingly, cf. below) as analogous to the “positron” solutions in quantum field theory.

Let us now raise (for the moment for no obviously good reason!) the question: do there exist “Majorana-like” solutions to the BdG equations, that is, solutions such that

$$\gamma_i^\dagger = \gamma_i. \quad (23)$$

It is clear from the definition (15) that this requires $u_i^*(\mathbf{r}) = v_i(\mathbf{r})$, (with appropriate spin-dependences, see below) and it furthermore follows from (16) that the corresponding energy eigenvalue E_i is exactly zero. However, these two conditions are not sufficient for an “interesting” Majorana; they would, for example, be satisfied by an ordinary Bogoliubov quasiparticle created in a “polar” p -wave superfluid (which has no particularly interesting topological properties) exactly at a node of the gap $\Delta(\mathbf{k})$, but one would not normally call such a quasiparticle a “Majorana”. What is missing in the above definition is that the solutions of the BdG equations are spatially *localized*, i.e., that both $u(\mathbf{r})$ and $v(\mathbf{r})$ tend to zero exponentially outside a small spatial region,¹ typically a volume $\sim \xi^d$ where ξ is the Cooper pair radius and d the spatial dimension. It turns out that in addition to the requirement that the pair spin structure is a triplet [necessary to guarantee the self-conjugacy condition (23)], such localized solutions only occur if the pair wave function (order parameter) has a sufficiently interesting structure, typically involving spontaneous breaking of time-reversal invariance (TRI).

At this point, rather than trying to review the general picture, let me specialize to what seems to be the most promising state for the real-life realization of MFs, namely the so-called “ $p + ip$ ” state. This state is characterized by the fact that either there is only a single spin state involved, or the amplitudes for $\uparrow\uparrow$ and $\downarrow\downarrow$ pairs may be treated as independent, and that as the name implies, in homogeneous conditions the order parameter $\Delta(\hat{p})$ written as a function of the direction of relative momentum $\mathbf{p}$ on the Fermi surface has the form

$$\Delta(\hat{p}) \propto \hat{p}_x + i\hat{p}_y \quad (24)$$

thereby violating (*inter alia*) the time-reversal invariance of the mf Hamiltonian [or of the original one of Eqs. (3), which for now we assume does not include TRI-violating terms]. The “ $p + ip$ ” state is believed to describe the A phase of superfluid ^3He and, (possibly, though this is controversial), the superconducting state of the metal Sr_2RuO_4 ; in the future it may be possible to realize a ($p + ip$) state of an ultracold Fermi gas which has only a single spin population paired.

In the case of ^3He -A and Sr_2RuO_4 , which contain both types $|\uparrow\uparrow\rangle$ and $|\downarrow\downarrow\rangle$ of Cooper pairs, it is believed (and in the latter case consistent with experiment (Jang et al., 2011)) that the system may sustain so-called “half-quantum vortices” (HQVs), that is, configurations in which (say) the $\uparrow\uparrow$ pair wave function exhibits a simple vortex similar to those realized in the Bose system ^4He , while that of the $\downarrow\downarrow$ pairs remains perfectly uniform. If this is so, then it appears that Majorana-type solutions not only can but must exist in the vicinity of these vortices (and possibly on the boundary of the system, if the number of vortices is odd). The general proof of this statement follows from the celebrated Atiyah-Patodi-Singer theorem in algebraic topology, but for any specified form of the order parameter near the vortex the existence of these solutions can be established by directly solving the BdG equations (18) (see Refs. (Kopnin and Salomaa, 1991; Volovik, 1999)).

The most exciting consequence of the existence of these MFs in a condensed-matter context is the prospect of possibly being able to use them for topological quantum computing (TQC), that is, a form of quantum computing in which the ubiquitous decoherence is frustrated by burying the relevant quantum information in strongly entangled many-body degrees of freedom in a way which is topologically protected. Why might MFs be a good prospect for TQC? There are essentially two major reasons (within the standard mf treatment, cf. below):

- (1) Because a MF is an exactly equal superposition of particle and hole, it is undetectable by any local probe.
- (2) MFs should behave under braiding as “Ising anyons”: if two HQVs each carrying a MF, are interchanged, the phase of the many-body wave function is changed (relative to the zero-MF state) by $\pi/2$; note this is different from the standard result of π which one would obtain for ordinary fermions.

This then leads to the following scheme to create a TQC (for details see Ref. (Stone and Chung, 2006)):

- (1) Create a set of HQVs, with and without MFs on them.
- (2) Braid the vortices adiabatically.
- (3) Recombine them and “measure” the result.

¹Or in some cases away from the boundary.

Then provided that during the braiding processes, the HQVs are kept at mutual distance $\gg \xi$, all decoherence should be proportional to $\exp(-L/\xi)$ and thus at least a class² (Nayak et al., 2008) of quantum computing operations will be topologically protected.

The above is an extremely “potted” version of the standard wisdom concerning MF in condensed matter physics. Now for a few comments:

What exactly is a MF?

Recall: its creation operator $\gamma_i^\dagger$ satisfies (since $E_i = 0$ exactly) the equation

$$\left[\widehat{\mathcal{H}}, \gamma_i^\dagger \right] \hat{\psi}_{\text{even}} \rangle = 0. \quad (25)$$

But this equation actually has two possible interpretations: the more obvious one is that $\gamma_i^\dagger$ creates an odd-number-parity state (a Bogoliubov quasiparticle) with energy exactly equal to that of the even-parity one. However, an equally viable interpretation is that $\gamma_i^\dagger$ simply annihilates the ground state (“pure annihilator”)! Now it is in fact easy to show (cf. Ref. (Leggett, 2010)) that neither of these possibilities can satisfy the self-conjugacy condition $\gamma_i^\dagger = \gamma_i$. To satisfy it, we must superpose the two possibilities: that is, formally, a MF is simply a quantum superposition of a “real” Bogoliubov quasiparticle with zero energy and a pure annihilator.

Consider now a situation in which we have just two HQVs, labeled 1 and 2, arbitrarily far apart. There exists on each vortex a Majorana solution, $\gamma_1^\dagger$ and $\gamma_2^\dagger$, respectively. As we have just seen, neither of these individually corresponds to creation of an extra zero-energy Bogoliubov quasiparticle. However, the combination

$$\alpha^\dagger \equiv \gamma_1^\dagger + i\gamma_2^\dagger \quad (26)$$

does so and satisfies the standard ACRs (5)! Thus, the two individual Majoranas, when suitably combined, indeed represent such a quasiparticle. The curious point is that this single extra fermion is spatially “split”: it has support from two very different regions of space. In this light, the “braiding” of two HQVs each carrying an MF may be regarded as the rotation through π of this zero-energy fermion (note that the predicted phase change of $\pi/2$ is exactly the mean of what we would expect, for the “standard” double-well case, for the symmetric and antisymmetric combinations of the states localized on 1 and 2, respectively).

An intuitive appreciation of the nature of MFs may be obtained by considering the “Kitaev quantum wire” (Kitaev, 2001), a set of equally spaced sites described by the BdG-type Hamiltonian

$$\widehat{\mathcal{H}} = \sum_i t_i (a_i^\dagger a_{i+1} + \text{h.c.}) + \sum_i \Delta_i (a_i^\dagger a_{i+1}^\dagger + \text{h.c.}) \quad (27)$$

with the special choice $t_i = \Delta_i \equiv X_i$ (but the X_i are not necessarily identical). Let us start with a ring geometry [Fig. 1 (a)]. Then the Bogoliubov quasiparticles are created by the operators

$$\alpha_i^\dagger \equiv (a_i^\dagger - a_i) + (a_{i-1}^\dagger + a_{i-1}) \quad (28)$$

and have excitation energies X_i ; note that they are localized on the links rather than the sites.

Now, imagine that we gradually turn down to zero the “strength” X_i of some link i , say 0, [see Fig. 1B]. There is still a fermionic (Bogoliubov) excitation associated with this link, but the energy of the corresponding odd-parity many-body state is degenerate with that of the even-parity ground state. Finally, we break the i -th link, and reconfigure the set of sites into Kitaev’s original open

Fig. 1 Origin of two Majorana fermions in the Kitaev quantum wire.

²As in other putative realizations of an Ising quantum computer, there is no complete topological protection: for that one needs to go to e.g., a “Fibonacci” QC, see e.g., Ref. (Nayak et al., 2008), Sec. IV-B

“wire” [Fig. 1C]; since the energy associated with this link is zero, the structure of the fermionic states cannot change and we must still have the zero-energy state. But where is it localized? In view of the symmetry of the situation, it must be localized equally on the two open ends of the wire! It should be mentioned that while this argument seems rather straightforward, the actual wave functions of both the even- and odd-parity ground states individually are highly entangled and the derivation of the correct forms is not entirely trivial.

I now turn briefly to the question of the experimental evidence for Majorana fermions. It should be stated at the outset that, at least as regards MF’s in topological superfluids/superconductors or related systems, the situation at the time of this writing is confused and controversial in the extreme. Whether by the time this chapter is published it will have become any clearer is anyone’s guess.

Let me first briefly review the physical systems which are of interest in this context. The one originally favored was a bulk topological superfluid, usually with an order parameter of the $p + ip$ type; this class includes bulk liquid $^3\text{He-A}$ and possibly some metallic superconductors, the originally favored candidate being Sr_2RuO_4 (single-layer strontium ruthenate, SRO). In such a system a necessary precondition for the appearance of MF’s would be the existence of half-quantum vortices (HQV’s). Unfortunately, to the present author’s knowledge there is to date no experimental evidence for HQV’s in the bulk A phase³ of ^3He , even in circumstances where theory would apparently predict them; the reason for this is not currently understood. In SRO the experimental picture seems internally inconsistent: magnetotorque experiments are naturally interpreted in terms of the appearance of (single) HQV’s, while recent Knight-shift experiments have given results which are widely interpreted as inconsistent with the spin triplet order parameter which is a necessary precondition for the latter. (For a discussion of this and other current puzzles related to SRO, see the mini-review (Leggett and Liu, 2021)). Other superconductors (e.g., UTe_2) have been identified as possibly having a $(p + ip)$ order parameter, but at the time of writing there is no direct evidence for HQV’s in them.

Actually, HQV’s as such are not essential to the existence of MF’s: all that is necessary is that the topological phase (e.g., the $p + ip$ phase) has one or more “edges” where it abuts on a region where the order parameter goes to zero. In the case of HQV’s, this region is the vortex core; however, the physical boundary of the sample can play a similar role. This realization has led to a proposal (Sau et al., 2010) which has attracted much interest in the experimental community, namely that a suitable system might be a semiconducting wire with strong spin-orbit interaction in proximity to a simple BCS superconductor. In this case the combination of the proximity effect and the spin-orbit interaction can generate in part of the wire a $p + ip$ -like (topological) superconducting state; while the rest of the wire remains normal; the two Majoranas are then predicted to reside at the edges of the topological region. In part because of the rich variety of parameters which can be tuned so as to affect the predicted properties of the MF’s, this idea has generated over the last decade a large number of experiments which use this setup to attempt to detect the latter; in most of these the raw data has been the current-voltage (I-V) characteristics of the wire as a function of spin-orbit interaction, s-wave gap, magnitude and direction of the magnetic field etc., and in many of the papers in question evidence for the existence of MF’s has been claimed. Unfortunately, the logic underlying these claims has mostly been of the “what else could it be?” variety, and there have been plenty of theoretical papers proposing other things it could be. In addition, in many cases the selection procedures used in the reporting of the data have been questioned (for a hard-hitting critique by an active worker in the field, see Ref. (Frolov, 2021)). So at this point the jury seems to be still out on these claims.

If one does not find spectroscopic (I-V) experiments particularly conclusive, an alternative is to look for evidence of behavior which is predicted to be qualitatively different for MFs and for ordinary quasiparticles. One possibility which has been suggested concerns Josephson circuits whose geometry and topology permits MFs, for example, some generated using p -wave-like superconductivity: the current-phase relation $I(\varphi)$ of such circuits is predicted to have not just the straightforward “ 2π -periodicity” in the Cooper-pair phase drop φ , but an extra 4π -periodic component. Unfortunately, when translated into the language of flux Φ , this simply corresponds to the generic h/e periodicity required by the Byers-Yang theorem, so it is not clear that its observation would be particularly definitive.

At first sight, a unique signature of the presence of a pair of MFs might seem to be the phenomenon of “teleportation”: since the corresponding single zero-energy Bogoliubov quasiparticle is delocalized between two spatially very distant sites, one might imagine that a “cause” at HQV 1, say the addition of an extra electron, might have “effects” at HQV 2 within a very short time compared to the time $\Delta t \sim L/v_F$ for ordinary physical impulses to travel the distance L between the HQVs (v_F = Fermi velocity). Unfortunately, there seem to be a number of reasons to doubt these conclusions, and the relevant theoretical community appears at the time of writing to be split/confused about it. In sum, while there is some circumstantial evidence for MFs in condensed matter physics, their existence cannot be said to have been established beyond reasonable doubt. Probably, the community will be totally convinced of their existence only if and when their predicted behavior under braiding is definitively established; at the time of writing several experimental groups are working toward this goal.

All the discussion up to this point has been within the framework of the standard mean-field approach to superconductivity (or fermion superfluidity). Actually, the present author has some doubts as to whether this approach is adequate for the MF problem, and it may be appropriate to conclude this chapter by explaining briefly why.

The problem lies in the very notion of spontaneously broken $U(1)$ symmetry (SBU(1)S). To recap, if we proceed as above using this idea, we relax particle number conservation and thus write the even-parity ground state in the form

³A 2016 paper (Autti et al., 2016) claims evidence for HQV’s in a different phase (the so called polar phase, believed to be unstable in bulk) in the pores of a certain kind of aerogel; while this phase as such is believed not to sustain MF’s, a modification of it might do so.

$$\Psi_{\text{even}} \sim \sum_{N=\text{even}} C_N \Psi_N \quad (29)$$

this then allows us to seek the simplest odd-parity states in the form

$$\gamma_i^\dagger = \int d\mathbf{r} \left[u_i(\mathbf{r}) \hat{\psi}^\dagger(\mathbf{r}) + v_i(\mathbf{r}) \hat{\psi}(\mathbf{r}) \right]. \quad (30)$$

But in real life, SBU(1)S is a myth! Indeed, if we consider a system contained in a well-defined volume, then either the boundaries of that volume are real physical walls, in which case a rigorous superselection rule forbids any nontrivial form of Eq. (29), or they are not, in which case, while the reduced density matrix of the system in the number representation may have different nonzero elements along the diagonal, ($\rho_{NN} \neq 0$ for several N), its *off-diagonal* elements $\rho_{NN'} (N \neq N')$ are rigorously zero and hence $\hat{\rho}$ cannot correspond to the ansatz (29). This state of affairs does not matter too much while we are considering only the even-parity states, since we can use the “Anderson trick” to write

$$\hat{\psi}_N \sim \int d\varphi \hat{\psi}_{\text{even}}(\varphi) e^{-iN\varphi} \quad (31)$$

[where φ is the overall phase of the pair wave function as defined under the assumption of SBU(1)S]. Similarly, it does not matter to the extent that we consider only the odd-parity situation (where a similar trick is possible). But if we want to discuss the *relation* between the even- and odd-parity states (which is the crux of what we have been doing above) it may be fatal! An example of a situation where the use of (30) leads to contradictions is the theory of NMR of a surface MF in $^3\text{He-B}$ (Taylor et al., 2015).

The problem may be fixed by properly taking into account the effect of the condensate, in particular by replacing formula (15) for $\gamma_i^\dagger$ by

$$\gamma_i^\dagger = \int d\mathbf{r} \left[u(\mathbf{r}) \hat{\psi}^\dagger(\mathbf{r}) + v(\mathbf{r}) \hat{\psi}(\mathbf{r}) C^\dagger \right], \quad (32)$$

where the operator $C^\dagger$ creates an extra Cooper pair so as to conserve total particle number. This makes essentially no difference in simple situations such as that of a BCS s -wave condensate at rest, in which the Cooper pairs have no “interesting” properties, but the moment they have a nontrivial degree of freedom (spin, center-of-mass momentum, angular momentum, etc.) it may change the picture qualitatively. But the very existence of MFs rests on the fact that the pairs indeed have “interesting” properties!

In this situation, we really need to go back to first principles and examine how the replacement of (15) by (32) (and also the question of whether $C^\dagger$ is simply the same quantity as appears in the even-parity ground state wave function) affects the “established” arguments about MFs and TQC. A preliminary conclusion is that it probably does not affect the existence of MFs (though they are no longer strictly their own antiparticles), but it may well destroy much of the current orthodoxy concerning their local undetectability, behavior under braiding, etc. This is work waiting to be done.

Acknowledgments

I am very grateful to Prof. Tapash Chakraborty and Prof. Martin Greiter for assistance in the preparation of the manuscript.

Abstract

This chapter reviews Majorana fermions emergent in insulating magnets, particularly the Kitaev quantum spin liquid. The Kitaev model, an $S = 1/2$ quantum spin model on a honeycomb lattice, can be solved by introducing four Majorana fermions. Three of them consist of local gage fields defined on the bonds of the honeycomb lattice, and they are local conserved quantities. One of the four Majorana fermions moves freely on the lattice under fixed gage fields. Thus, the elementary excitations are governed by the two quasiparticles, itinerant Majorana fermions and local gage fields, which are interpreted as fractionalization of quantum spin. The signatures of the Majorana fermions can be observed in thermodynamic and dynamical properties, such as the specific heat, dynamical spin structure factor, and Raman spectrum. Moreover, the Majorana fermion system becomes topologically nontrivial by applying magnetic fields, and an excited gage field traps an isolated Majorana fermion (Majorana zero mode). This causes a half quantization of thermal Hall coefficient, which should be one of the most demonstrable signatures of the existence of Majorana fermions. Transition metal compounds with strong spin–orbit coupling are proposed as candidate materials whose magnetic properties are dominantly governed by the Kitaev model. Different experimental probes have observed manifestations of Majorana fermions in these materials. However, further investigations are needed in the candidate materials to establish the presence of the Majorana fermions, particularly Majorana zero modes, which can be applied to topological quantum computing.

Key points

- The ground state of the Kitaev model is a quantum spin liquid with short-range spin correlations.
- Elementary excitations from the Kitaev quantum spin liquid are two quasiparticles: itinerant Majorana fermions and local gauge fields.
- The itinerant Majorana fermions and local gauge fields are emergent quasiparticles due to spin fractionalization.
- An applied magnetic field induces the band structure of the emergent Majorana fermions to be topologically nontrivial and the excitation of local gauge fields to be accompanied by a Majorana zero mode.
- The Kitaev model is believed to be realized in transition metal compounds with strong spin–orbit coupling.
- Recent experiments for the Kitaev candidate materials have observed signatures of the existence of Majorana fermions.

Introduction

In strongly correlated electron systems, quasiparticles with distinct natures appear as elementary excitations due to electron correlations despite electrons being merely Fermi–Dirac particles. In particular, insulating magnets possess quasiparticles originating from magnetic excitations. For example, collective excitations from a magnetic order are known as magnons, which are bosonic excitations. On the other hand, it has been suggested that fermionic excitations are present as elementary excitations in quantum spin liquids (QSLs), where any magnetic orders do not appear even at zero temperature. Such quasiparticles are called spinons, and the signatures, such as a T -linear specific heat and continuum in excitation spectra, have been observed in candidate materials of the QSL, although they are insulating (Yamashita et al., 2008, 2010; Han et al., 2012; Isono et al., 2014).

In QSLs, other quasiparticles with striking features can emerge due to strong quantum fluctuations. For example, a Majorana fermion can be realized as a quasiparticle. A Majorana fermion was introduced by E. Majorana in 1937 as a real-valued solution of the Dirac equation (Majorana, 1937). The characteristic, unlike conventional fermions, is that it is identical to its own antiparticle,

and thereby, the Majorana particle is a charge-neutral fermion. In the field of particle physics, neutrinos are the candidates for Majorana fermions. On the other hand, condensed matter physics also provides a playground for Majorana fermions as elementary excitations.

Here, we briefly show the fundamental properties of Majorana fermions. We introduce two Majorana fermion operators, γ_1 and γ_2 . Owing to the Majorana nature, creation and annihilation operators are identical: $\gamma_i = \gamma_i^\dagger$ ($i = 1, 2$). Moreover, as they are fermion operators, these satisfy the following relations: $\{\gamma_i, \gamma_j\} = 2\delta_{ij}$. Using the two Majorana fermions, a fermion operator f is introduced as

$$\begin{aligned} f &= \frac{1}{2}(\gamma_1 + i\gamma_2) \\ f^\dagger &= \frac{1}{2}(\gamma_1 - i\gamma_2). \end{aligned} \quad (1)$$

The relations indicate that the degree of freedom of a Majorana fermion is half that of a conventional fermion.

In condensed matter physics, one of the most familiar systems with Majorana quasiparticles is the Kitaev model. This model was introduced by A. Kitaev in 2006 for realizing the toric code with topological order and a system with non-Abelian anyons, which is applicable to topological quantum computing (Kitaev, 2006). This model is a simple quantum spin model, but the ground state is a QSL due to strong quantum fluctuations, and its elementary excitations are described as Majorana fermions (Nussinov and van den Brink, 2015; Hickey and Trebst, 2022; Hermanns et al., 2018; Knolle and Moessner, 2019; Takagi et al., 2019; Motome and Nasu, 2020). In the following section, we review the fundamental properties of the Kitaev model.

Majorana fermions in Kitaev model

The Kitaev model is a quantum spin model, which describes interactions between neighboring $S = 1/2$ spins located on sites of a honeycomb lattice (Kitaev, 2006). On this lattice, there are three types of bonds connecting sites i and j , which we term x bond $\langle ij \rangle_x$, y bond $\langle ij \rangle_y$, and z bond $\langle ij \rangle_z$ [see Fig. 1A]. Using these representations, the Hamiltonian is given by

$$\mathcal{H}_K = -J_x \sum_{\langle ij \rangle_x} S_i^x S_j^x - J_y \sum_{\langle ij \rangle_y} S_i^y S_j^y - J_z \sum_{\langle ij \rangle_z} S_i^z S_j^z, \quad (2)$$

where S_i is an $S = 1/2$ spin on site i and J_μ ($\mu = x, y, z$) is a coupling constant on the μ bonds, as shown in Fig. 1A. We assume that all exchange constants are positive for simplicity. As shown in Eq. (2), the Kitaev model comprises bond-dependent Ising-type interactions. This leads to a kind of frustration even in the ferromagnetic couplings with $J_\mu > 0$, where all bond energies cannot be minimized simultaneously. The situation expects an exotic quantum ground state. Indeed, the ground state of the Kitaev model is exactly shown to be a QSL.

In the Kitaev model, there is a local conserved quantity on each hexagon in the honeycomb lattice, which is given by

Fig. 1 (A) Bond-dependent interactions of the Kitaev model defined on a honeycomb lattice. The x , y , and z bonds with exchange constants J_x , J_y , and J_z are shown by blue, green, and red, respectively. $\mathbf{a}_+$ and $\mathbf{a}_-$ are the primitive transformation vectors of the honeycomb lattice. (B) Schematic picture of Majorana fermion representation of an $S = 1/2$ quantum spin in the Kitaev model. The quantity u_{ij} is defined on each bond, and the flux W_p is on each hexagon plaquette (Kitaev, 2006).

$$W_p = 2^6 \prod_{i \in p} S_i^{\mu_i}, \quad (3)$$

where W_p is given by the product of six spins on hexagon plaquette p , and μ_i is the spin component corresponding to the bond not belonging to the hexagon. This quantity is called “flux” or “vison” and satisfies the following relations: $W_p^2 = 1$ and $[W_p, W_{p'}] = 0$ with $p \neq p'$ in addition to $[\mathcal{H}_K, W_p] = 0$. These relations indicate that the eigenstates of the Kitaev model are characterized by the set of the eigenvalues of W_p taking ± 1 for all hexagon plaquettes. The presence of the local conserved quantities straightforwardly results in the absence of long-range spin correlations (Baskaran et al., 2007). Hence, the Kitaev model exhibits a QSL ground state.

While all eigenstates of the Kitaev model are assigned by flux configurations $\{W_p = \pm 1\}$, the dynamics in each fixed flux sector can be described by using Majorana fermions. Let us introduce four Majorana fermions $\{c_i, b_i^x, b_i^y, b_i^z\}$ at each site [see Fig. 1B] and represent the spin operator as

$$S_i^\mu = \frac{i}{2} b_i^\mu c_i. \quad (4)$$

Here, the commutation relations of the spin operators are reproduced by those of Majorana fermions. Note that spin operators also satisfy the following equation:

$$i = 2^3 S_i^x S_i^y S_i^z = i b_i^x b_i^y b_i^z c_i \equiv iD, \quad (5)$$

which indicates that original spin space enforces $D = +1$ for all site. On the other hand, $D = b_i^x b_i^y b_i^z c_i$ takes ± 1 in the Majorana representation, suggesting that the present Majorana representation extends the model space to that with $D = \pm 1$. This implies that the projection onto the model space with $D = +1$ is essential to obtain correct results.

Using Eq. (4), the Hamiltonian given in Eq. (2) is rewritten as

$$\mathcal{H}_K = \frac{i}{4} \sum_{\langle ij \rangle_\mu} J_\mu u_{ij} c_i c_j, \quad (6)$$

where u_{ij} are given by $u_{ij} = i b_i^\mu b_j^\mu$ on μ bonds. Each u_{ij} commutes with the Hamiltonian and satisfies $u_{ij}^2 = 1$, and therefore, it is a Z_2 conserved quantity on each bond. This indicates that the dynamics of the Majorana fermion c_i is separated from that of b_i^μ although the spin operator, which is an observable, is written as the product of these two Majorana fermions. This is interpreted as the fractionalization of spin into two Majorana fermions. Note that u_{ij} is related to the flux operator given in Eq. (3) as follows:

$$W_p = \prod_{\langle ij \rangle \in p} u_{ij}, \quad (7)$$

where the product is taken for the six bonds of the hexagon p . The flux operator W_p is written by the spin operators, and hence it is an observable. On the other hand, u_{ij} is not directly given by the spin operators and is not observable. Moreover, the number of W_p is $N/2$, but that of u_{ij} is $3N/2$, where N is the number of sites, indicating the presence of the redundancy in u_{ij} . Thus, u_{ij} is regarded as a Z_2 gauge field.

Since u_{ij} is a Z_2 local conserved quantity, this can be treated as a classical number taking ± 1 in Eq. (6). From Lieb’s theorem, one can prove that the flux configuration with all $W_p = +1$ gives the lowest energy manifold. This configuration is reproduced by all $u_{ij} = +1$. In this subspace, the Hamiltonian is written as

$$\mathcal{H}_K = \frac{i}{4} \sum_{\langle ij \rangle_\mu} J_\mu c_i c_j, \quad (8)$$

which is regarded as a free Majorana fermion system. By introducing the Fourier transformation of c_i , the Hamiltonian is diagonalized as

$$\mathcal{H}_K = \sum_k \varepsilon_k \left(d_k^\dagger d_k - \frac{1}{2} \right), \quad (9)$$

where $\varepsilon_k = |J_x e^{ik \cdot \mathbf{a}_+} + J_y e^{ik \cdot \mathbf{a}_-} + J_z|/2$ with $\mathbf{a}_\pm = (\pm 1/2, \sqrt{3}/2)$ being the primitive transformation vectors shown in Fig. 1A. By changing the exchange constants, the band structure ε_k exhibits both gapless and gapped. In the isotropic case with $J_x = J_y = J_z$, there are point nodes at the K and K’ points, as shown in Fig. 2. In general, in the case of $J_x \leq J_y + J_z$ and its cyclic permutations, the dispersion is gapless, and the excitation gap opens elsewhere. The phase diagram is presented in Fig. 3. As shown in this figure, the Kitaev model shows the gapless and gapped QSLs, determined by the spectrum of the Majorana fermion excitations. On the other hand, the excitation energy of fluxes is nonzero regardless of the values of the exchange constants. This leads to the fact that spin excitations should be gapped because the γ component of the spin operators is given by the product of c_i and b_i^y , the latter of which changes the flux configuration. The dynamical spin structure factor is calculated exactly in the Kitaev model (Knolle et al., 2014b), and it exhibits the spin gap, whose energy reflects the flux gap Δ_γ . The details are given later. The presence of the spin gap is consistent with short-range spin correlations even in the gapless phase, where the excitation spectrum of the Majorana fermion c_i is gapless.

In the Kitaev model without magnetic fields, the dynamics of Majorana fermions c is separated from that of b^y . This feature is the origin of the exact solvability. Since the spin operators hybridize these dynamics, the introduction of the magnetic fields renders the

Fig. 2 Dispersion relation $\epsilon_{\mathbf{k}}$ in Eq. (9) without magnetic fields and $\tilde{\epsilon}_{\mathbf{k}}$ in Eq. (12) with the effective magnetic field, which are shown by blue and brown, respectively. The red dashed line represents the horizontal axis of Fig. 4A.

Fig. 3 Phase diagram of the Kitaev model without magnetic fields on the plane of $J_x + J_y + J_z = 1$ (Kitaev, 2006).

system unsolvable. To avoid this difficulty, one considers the effect of the magnetic field as a perturbation in the ground-state flux sector with all $W_p = +1$. The third-order perturbation for the Zeeman term $\mathcal{H}_h = -\sum_i \mathbf{h} \cdot \mathbf{S}_i$ leads to the effective magnetic field, which is given by

$$\mathcal{H}_h^{\text{eff}} = -\kappa \sum_{[ijk]_{\mu\mu'}} S_i^\mu S_j^{\mu''} S_k^{\mu'}, \quad (10)$$

where κ is the effective magnetic field proportional to $h^x h^y h^z / \Delta_f^2$, and $[ijk]_{\mu\mu'}$ stands for neighboring three sites on the two bonds $\langle ij \rangle_\mu$ and $\langle jk \rangle_{\mu'}$ with μ'' neither μ nor μ' . This effective Zeeman term is rewritten by the Majorana representation of the spin operators given in Eq. (4) as

$$\mathcal{H}_h^{\text{eff}} = \frac{i\kappa}{8} \sum_{[ik]} c_i c_k, \quad (11)$$

in the case with all $W_p = +1$, where $[ik]$ represents the next nearest neighbor pair for sites i and k . The total Hamiltonian $\mathcal{H}_K + \mathcal{H}_h^{\text{eff}}$ describes the Majorana fermions with nearest neighbor hopping J_μ and next nearest neighbor hopping κ on the honeycomb lattice, which is regarded as a Majorana version of the Haldane model showing the quantum Hall effect (Haldane, 1988). One can expect the topologically nontrivial band structure originating from the Majorana fermions in the presence of the effective magnetic field. Indeed, the band structure is modified by introducing the magnetic field as

$$\tilde{\epsilon}_{\mathbf{k}} = \sqrt{\epsilon_{\mathbf{k}}^2 + \Delta_{\mathbf{k}}^2}, \quad (12)$$

where $\Delta_{\mathbf{k}} = \kappa[\sin(-\mathbf{k} \cdot \mathbf{a}_+) + \sin(\mathbf{k} \cdot \mathbf{a}_-) + \sin(\mathbf{k} \cdot (\mathbf{a}_+ - \mathbf{a}_-))]$. In the case of $\kappa = 0$, there are two point nodes for the isotropic case with $J_x = J_y = J_z$ as mentioned before. The effective magnetic field opens the gap at these points, given by $3\sqrt{3}\kappa/4$. As a result, the Chern number of the fermionic band is quantized to ± 1 , and a chiral edge mode appears in the gap around the zero energy when open boundary conditions are imposed.

Note that a flux excitation traps a Majorana fermion with $W_p = -1$ at a hexagon plaquette p , which appears as a counterpart of the chiral edge mode. When the trapped Majorana fermion is localized and isolated, the energy should be zero. This implies that a flux excitation accompanies a Majorana zero mode in the presence of the effective magnetic field. Since the quantum states of Majorana zero modes can change in exchanging them, the composite quasiparticle consisting of a Majorana zero mode and an excited flux is regarded as a non-Abelian anyon. The exchange procedure called “braiding” should be achieved by manipulating the positions of excited fluxes and is known to be applicable to topological quantum computing.

Fingerprint of Majorana fermions

In this section, we show how the signature of Majorana fermions appears in the Kitaev QSL. In particular, we focus on the isotropic case with $J_x = J_y = J_z \equiv J$ hereafter. The Kitaev model hosts two elementary excitations: the itinerant Majorana fermion c_i and localized flux excitation W_p originating from the Majorana fermion b_i^μ . In the present case, the band structure of the itinerant Majorana fermions is gapless, whereas the localized flux excitations are gapped. As shown in Eq. (4), the spin operator is represented as the product of the two Majorana fermions, which indicates that spin excitations involve the dynamics of both of them. Thus, fingerprints of the Majorana fermions should appear in the spectrum of the dynamical spin structure factor, which is defined as

$$S(\mathbf{q}, \omega) = \frac{1}{N} \sum_{ij} \int_{-\infty}^{\infty} \frac{dt}{2\pi} \sum_{\mu\mu'} \langle S_i^\mu(t) S_j^{\mu'} \rangle e^{i\omega t - i\mathbf{q} \cdot (\mathbf{r}_i - \mathbf{r}_j)}, \quad (13)$$

where $\mathcal{O}(t) = e^{i\mathcal{H}_K t} \mathcal{O} e^{-i\mathcal{H}_K t}$ is the Heisenberg representation of an operator $\mathcal{O}$. This quantity corresponds to the spectrum of inelastic neutron scattering in experiments, and theoretically, it can be exactly evaluated using the Majorana representation in the Kitaev model (Knolle et al., 2014b, 2015). Fig. 4A shows the contour map of $S^{\mu\mu}(\mathbf{q}, \omega)$ on the plane of $\mathbf{q}$ and ω . There is a strong peak at $\omega \simeq 0.1J$ and a broad continuum around $\omega \sim J$. These two types of structure does not strongly depend on $\mathbf{q}$ because the long-range spin correlations beyond nearest neighbor sites are absent in the Kitaev model. The energy of the low-energy coherent peak is close to the flux gap, and the incoherent structure has a spectral weight up to $\omega \sim 1.5J$ corresponding to the bandwidth of the itinerant Majorana fermions c_i . Therefore, two Majorana fermions b_i^μ and c_i manifest themselves as distinctly different types of structure in $S^{\mu\mu}(\mathbf{q}, \omega)$.

In the dynamical spin correlations, the signatures of the two Majorana fermions are observed simultaneously, but separated observations for them are desired to clarify the presence of the fractionalization into Majorana fermions in the Kitaev QSL. One of the measurements capable of observing the quasiparticles separately is the Raman scattering. This is an optical measurement to obtain information on low-energy excitations by irradiating light and observing scattered light with a different frequency. The Raman spectrum $I_R(\omega)$ is given by a function of the frequency difference of the incoming and outgoing phonons, which is called the Raman shift ω . To calculate the Raman spectrum, Loudon and Fleury developed a theory for insulating magnets (Fleury and Loudon, 1968). In the Loudon–Fleury approach, the Raman operator is given by $\mathcal{R} = \sum_{\langle ij \rangle_\mu} (\boldsymbol{\varepsilon}_{\text{in}} \cdot \mathbf{d}^\mu) (\boldsymbol{\varepsilon}_{\text{out}} \cdot \mathbf{d}^\mu) J^\mu S_i^\mu S_j^\mu$, where $\boldsymbol{\varepsilon}_{\text{in}}$ and $\boldsymbol{\varepsilon}_{\text{out}}$ are the polarization vectors of the incoming and outgoing photons, and $\mathbf{d}^\mu$ are the vectors connecting the nearest neighbor sites (Knolle et al., 2014a; Perreault et al., 2015). Using the Raman operator, the Raman intensity $I_R(\omega)$ is given by

$$I_R(\omega) = \frac{1}{N} \int_{-\infty}^{\infty} \langle \mathcal{R}(t) \mathcal{R} \rangle e^{i\omega t} dt. \quad (14)$$

Note that this is independent of the polarization directions of the incoming and outgoing phonons in the isotropic case. Importantly, because the Raman operator commutes with all fluxes W_p , the itinerant Majorana fermions c_i are only excited in the Raman process. This characteristic is in stark contrast to the dynamical spin structure factor in Eq. (13); the spin operator does not commute with W_p . Thus, the itinerant Majorana fermions c_i are only excited in the Raman process, which is one of the striking features of the Raman scattering.

In the Kitaev model, the Raman spectrum in the Kitaev model is also calculated exactly based on the Loudon–Fleury approach. Fig. 4B shows the Raman intensity as a function of the Raman shift ω (Knolle et al., 2014a; Perreault et al., 2015). There is a broad continuum between 0 and $3J$, which is twice of the bandwidth of the itinerant Majorana fermions. This is understood from the fact that a phonon creates two Majorana fermions in the Raman process, and hence the spectral structure of the Raman scattering directly reflects the presence of the Majorana fermions and is unrelated to the flux excitations.

Fig. 4 (A) Dynamical spin structure factor $S(\mathbf{q}, \omega)$ on the plane of $\mathbf{q}$ and ω (Knolle et al., 2014b), and (B) intensity of the Raman spectrum $I_R(\omega)$ normalized by its maximum (Knolle et al., 2014a).

The topological properties of the Majorana fermions can be observed as a heat transport because the charge neutrality intrinsic in the Majorana fermion hinders observations by electric responses, but its flow can carry heat. Here, we focus on the thermal Hall effect, where a temperature gradient generates a heat current perpendicular to it. As discussed in the previous section, we show that the Majorana fermion system becomes topologically nontrivial in the presence of the effective magnetic field $\mathcal{H}_h^{\text{eff}}$. Here, we introduce the thermal Hall conductivity κ^{xy} defined by $\langle J_Q^x \rangle_{\nabla T} = \kappa^{xy} (-\nabla T)_y$, where ∇T is an applied temperature gradient along the y direction and $\langle J_Q^x \rangle_{\nabla T}$ is the expectation value of the x component of the heat current in the presence of the temperature gradient. In Majorana fermion systems with topologically nontrivial band structure with Chern number $C = +1$, the low-temperature thermal Hall conductivity is quantized as

$$\frac{\kappa^{xy}}{T} = \frac{\pi}{12} \frac{k_B^2}{\hbar}, \quad (15)$$

where k_B and $\hbar$ are the Boltzmann and reduced Planck constants, respectively (Nomura et al., 2012; Sumiyoshi and Fujimoto, 2013). In contrast, thermal Hall conductivity divided by T is quantized by $\frac{\pi}{6} \frac{k_B^2}{\hbar}$ at $T \rightarrow 0$ in conventional fermion systems, which is twice in the Majorana fermion system. The quantized thermal Hall conductivity Eq. (15) is the consequence of the nature inherent in a Majorana fermion, which carries a half degree of freedom of a conventional fermion. Therefore, the half-quantization of the thermal Hall conductivity can provide compelling evidence of realizing Majorana fermions.

The fractionalization of spin into itinerant Majorana fermions and flux excitations manifests itself in the temperature dependence. As mentioned, these two elementary excitations in Kitaev QSL have completely different energy scales. As a result, the entropy releases are expected to occur at different temperatures. The specific heat exhibits a double-peak structure in the specific heat, and half of the entropy is released at each peak (Nasu et al., 2014, 2015). The detailed analysis clarifies that the low-temperature entropy release originates from the flux excitations, and the high-temperature one corresponds to the itinerant Majorana fermions. The half-entropy release should also be convincing evidence of the fractionalization of spin into Majorana fermions in the temperature evolution of the Kitaev QSL.

Experimental realizations

The Kitaev model is believed to be realized in strongly correlated electron systems with the strong relativistic spin-orbit coupling (Jackeli and Khaliullin, 2009). We focus on transition metal ions with the t_{2g}^5 configuration in $4d$ or $5d$ orbitals, for example, Ir^{4+} and Ru^{3+} ions. Since the t_{2g} orbitals possess effective angular momentum with $l_{\text{eff}} = 1$, the t_{2g} orbital degeneracy is lifted into $j_{\text{eff}} = 1/2$ and $j_{\text{eff}} = 3/2$ states due to the strong spin-orbit coupling. There is a hole in the doubly degenerate $j_{\text{eff}} = 1/2$ states for the t_{2g}^5 configuration, and the degree of freedom of which state a hole occupies is described by introducing a pseudo-spin S . The effective interaction between pseudo-spins in neighboring transition metal ions is derived from a multiorbital Hubbard model by considering the second perturbation with respect to the hopping of t_{2g} electrons in the strong correlation limit. Suppose that each transition ion is surrounded by six ligand ions forming an octahedron with cubic symmetry, and neighboring octahedra share their edges. Moreover, one only considers the virtual hopping between t_{2g} electrons in neighboring sites via ligand ions located between the transition metal ions in the perturbation procedure. In these conditions, the interaction between the pseudo-spins is Ising-type, and the interacting component of the pseudo-spin depends on the bonding direction. When transition ions form a honeycomb lattice, the interactions between the pseudo-spins are given by the Kitaev model. As the candidate materials, iridium oxides A_2IrO_3 ($A = \text{Li}, \text{Na}$) (Singh and Gegenwart, 2010; Singh et al., 2012; Comin et al., 2012; Choi et al., 2012) and $\alpha\text{-RuCl}_3$ (Sears et al., 2015; Kubota et al., 2015; Sandilands et al., 2015; Majumder et al., 2015) were proposed, and thermodynamic and magnetic properties of them have been intensively investigated.

In these materials, magnetic orders appear at low temperatures while the ground state of the Kitaev model is a QSL. This is due to additional interactions, such as Heisenberg and off-diagonal symmetric interactions (Chaloupka et al., 2010, 2013; Rau et al., 2014; Winter et al., 2016). Nevertheless, the Kitaev interaction is believed to be predominant over these additional terms, and the signature of the Kitaev physics appears above the temperature of the magnetic ordering. For example, it has been reported that the specific heat exhibits a peak in addition to the low-temperature anomaly originating from the magnetic ordering in the iridium oxide Na_2IrO_3 (Mehlawat et al., 2017) and ruthenium compound $\alpha\text{-RuCl}_3$ (Do et al., 2017; Widmann et al., 2019). By integrating the specific heat around the high-temperature peak, the entropy release is estimated at about $0.5k_B \ln 2$, which is considered to be a manifestation of the spin fractionalization into Majorana fermions.

Signatures of Majorana fermions are also observed in excitation spectra as discussed in Section “Fingerprint of Majorana fermions”. Inelastic neutron scattering measurements have clarified that there is the continuum of magnetic excitations whose energy scale corresponds to the exchange energy in $\alpha\text{-RuCl}_3$, and this broad structure survives even above the critical temperature of the magnetic order (Banerjee et al., 2016, 2017). Since the dominant exchange energy originates from the Kitaev interaction, which is much larger than the energy scale of the critical temperature, the broad continuum is considered to correspond to the structure at $\omega \sim J$ of $S(q, \omega)$ in the Kitaev model [see Fig. 4A]. The results suggest that the neutron scattering observes excitations of the Majorana fermions. It has also been pointed out that the broad continuum in the candidate compounds should be explained by the magnon damping (Winter et al., 2017).

In addition to the neutron scattering, the Raman scattering measurement has also been performed in $\alpha\text{-RuCl}_3$ (Sandilands et al., 2015). Similar to the inelastic neutron scattering, the broad continuum has been observed in the Raman spectrum, which

corresponds to that of the Kitaev model shown in Fig. 4B. More interestingly, the temperature dependence of the spectral weight observed in α -RuCl₃ is well fitted using the Fermi distribution function (Nasu et al., 2016). The result implies that the experimentally observed broad continuum is attributed to fermionic excitations.

As mentioned in Section “Fingerprint of Majorana fermions”, the thermal Hall effect is crucial to clarify the presence of Majorana fermions in Kitaev candidate materials. When a topological chiral edge mode comes from a Majorana fermion, the thermal Hall coefficient is quantized. The value given in Eq. (15) is half of the case of a conventional fermion, which is a consequence of the presence of Majorana fermions. The half-quantization of the thermal Hall coefficient was reported in the Kitaev candidate material α -RuCl₃ (Kasahara et al., 2018). Furthermore, it was reported that the half quantization is also observed even when the magnetic field is applied on the plane of the temperature gradient and resultant heat current (Yokoi et al., 2021). Note that some research groups claimed that these results were reproduced (Yamashita et al., 2020; Bruin et al., 2022), but other groups reproduced a nonzero thermal Hall coefficient while they claimed the absence of its quantization. Instead, they provided another origin such as magnons or phonons (Hentrich et al., 2019; Czajka et al., 2021; Lefrançois et al., 2022; Czajka et al., 2022). Thus, further investigations are need to clarify the presence of the half quantization, which is compelling evidence of the presence of Majorana fermions in real materials.

Conclusion

In summary, we have reviewed the properties of Majorana fermions emergent in the Kitaev QSL and how to observe them in real compounds. The Kitaev model possesses two elementary excitations, itinerant Majorana fermions, and flux excitations. The itinerant Majorana fermions are accessible from several experimental probes, and the presence is becoming established. The next step is the local manipulation of a Majorana fermion (Majorana zero mode), which is essential to topological quantum computing. We hope that in the future, Majorana fermions in condensed matter physics, including QSLs, will be applied in various fields, taking advantage of their unique features.

Abstract

This chapter explores the origins and descriptions of collective modes, traversing the vast spectrum of physics from the subatomic particles in the Standard Model to quasiparticle phenomena in condensed matter. Spontaneous symmetry breaking (SSB) plays a crucial role, as Goldstone modes and Higgs bosons emerge, shaping our understanding of matter's properties across various energy scales. We discuss their origins and provide explicit examples in field theories and in solid-state physics. This interdisciplinary exploration enhances our comprehension of the underlying laws of nature, bridging the realms of condensed matter and high-energy physics.

Key points

- Explore the origins and descriptions of collective modes in physics, spanning field theories to quasiparticle phenomena in condensed matter.
- Discuss the role of spontaneous symmetry breaking (SSB) in the emergence of Goldstone modes and Higgs bosons, shaping our understanding of matter's properties across energy scales.
- Provide explicit examples of SSB in field theories and solid-state physics.
- Enhance comprehension of the underlying laws of nature by bridging condensed matter and high-energy physics.
- Investigate the crucial role of collective excitations, such as Goldstone and Higgs modes, in understanding matter at low and high energy scales.
- Highlight the potential of quasiparticle excitations in both condensed matter and high-energy physics to uncover new physics beyond the Standard Model such as for scattering targets for low-mass dark matter, expanding the parameter space for dark matter searches.

Introduction

The use of a particle description of our physical universe is common across all lengthscales in physics ranging from quarks at the subatomic scale to astronomical objects such as stars (Grossman, 2014). There are intriguing analogies between the formulation of quantum field theory (QFT) for elementary particles and many-body theory for condensed matter systems. For instance, QFT associates elementary particles such as photons (particles of light) and gravitons (particles mediating gravitational forces) with quanta of radiation fields and gravitational fields, respectively. These particles are intricately linked to the fundamental forces of nature, and in the case of gravitons have not yet been directly observed (Carney, 2022). On the other hand, condensed matter systems exhibit collective behaviors and waves that can be effectively described using many-body theory. Here, entities like phonons

(quanta of lattice vibrations) and plasmons (quanta of collective electronic oscillations) emerge through the quantization of these collective waves. Unlike elementary particles, these quasiparticles arise as collective excitations within the solid-state structure, influenced by interatomic interactions and the underlying lattice structure.

The concept of spontaneous symmetry breaking (SSB) plays a significant role in the description and understanding of quasiparticle excitations in this wide range of physical systems, from the microscopic to the galactic (Guralnik et al., 1968). Goldstone modes are perhaps the most well-known example of collective excitations that arise from SSB as they play a fundamental role in determining the properties of materials at low temperatures. On the other hand, in high-energy physics, SSB is deeply connected to the Higgs mechanism, which gives rise to the Higgs boson and is responsible for the spontaneous breaking of the electroweak symmetry in the Standard Model. The Higgs mechanism also has substantial implications in condensed matter physics, where Higgs modes are now the emergent quasiparticle excitations.

At low energies, the study of quasiparticle excitations, such as Goldstone and Higgs modes, is crucial for our understanding of matter. These collective excitations can also provide new insights into the behavior of matter at high-energy scales, such as those found in collider experiments. Exploring quasiparticle excitations in both condensed matter and high-energy physics allows us to better understand and connect the fundamental laws of nature across lengthscales. Condensed matter systems can provide a unique opportunity to study quasiparticle excitations in more easily accessible table-top experiments while high-energy physics can provide new insights into the nature of matter and the universe at extreme scales. For instance, an emerging area in high-energy physics is the use of quasiparticle excitations in condensed matter systems as scattering targets for low-mass dark matter (DM). This bridging of high- and low-energy physics has the potential to expand the parameter space for DM searches and uncover new physics beyond the Standard Model.

Spontaneous symmetry breaking

SSB occurs when the underlying laws of a physical system exhibit a symmetry, but the system itself behaves in a way that apparently breaks that symmetry. While this may sound paradoxical, it is in fact a common occurrence in nature and plays a crucial role in many areas of physics, from particle physics to condensed matter physics.

The concept of symmetry breaking has roots far deeper than its modern usage in contemporary physics, tracing back to Aristotle's work, "On the Heavens 295b," circa 350 BC. Aristotle satirically posits that an individual, situated equidistantly between food and drink, would rather perish than disrupt the symmetry and choose between the two options (Rescher, 2013). This ancient paradox was later recast by philosophers as a commentary on moral determinism, replacing the famished and parched human with a donkey (as illustrated in Fig. 1). At the top of the "wine bottle" potential, there is full rotational symmetry—the landscape appears identical from the donkey's perspective even as he rotates about his position. However, a minor perturbation—perhaps prompted by the donkey's own need for sustenance—can cause the donkey to topple down the potential, landing at a select point in the circle making up the trough at the bottom of the potential. Now the situation has dramatically changed: as the donkey rotates, each direction presents a distinct view. The ground-state solution no longer exhibits rotational symmetry even though the potential hasn't

Fig. 1 Buridan's donkey sitting on top of the "wine bottle" potential. In the high-symmetry state on top of the potential, the system has full rotational symmetry. Falling down the hill results in a choice of ground state which at the same time breaks rotational symmetry.

changed. Luckily, the donkey can traverse the flat trough in a complete circle without expending energy. Upon descending the potential, the system’s symmetry remains unchanged; however, the particular choice of ground-state solution breaks this symmetry. Nature’s predilection for lower energy solutions resolves the indecisive philosopher’s quandaries.

SSB occurs when the ground state of a system appears not to share the same symmetries as the theory that describes it. In these cases, a continuous transformation, such as rotation or translation, that leaves the equations of motion unchanged does not leave the ground state unchanged. We see SSB across all fields of physics, and most frequently discussed in condensed matter physics and high-energy physics. A common example of SSB is the paramagnetic to ferromagnetic phase transition in a magnetic material (see Fig. 2). Above the Curie temperature, T_C , the spins on each site are randomly oriented. The system has rotational symmetry with a net magnetization of zero. As the system is cooled below T_C , it undergoes a phase transition where the spins now spontaneously order and point in a particular direction. This choice of ground state breaks the rotational symmetry and results in a net magnetization in the direction of the broken symmetry. Table 1 gives several further examples of SSB at disparate lengthscales and the corresponding broken symmetries for each case.

Goldstone and Higgs modes

Nambu–Goldstone modes

Upon symmetry breaking, we noted that the donkey now has the freedom to wander around the base of the potential—this new excitation is a direct result of the SSB. Such an excitation is referred to as a Goldstone mode, also known as a Nambu–Goldstone boson or a Goldstone boson (Nambu, 1960; Goldstone, 1961). It is a collective excitation in a theory that appears when a continuous symmetry is spontaneously broken. Goldstone modes are massless or nearly massless fluctuations that are associated with this broken symmetry. Due to their low energy cost, they can propagate throughout the system, giving rise to long-range correlations and other emergent phenomena. In condensed matter, Goldstone modes are used to describe an array of collective excitations in systems such as crystals, magnets, and superfluids.

Example: Goldstone modes in $U(1)$ scalar field theory

To illustrate the appearance of Goldstone modes with SSB, we consider the case of a complex scalar field, $\phi(x)$ which is charged under $U(1)$ global symmetry:

$$\phi(x) \rightarrow e^{i\theta} \phi(x)$$
 (1)

Fig. 2 Paramagnetic to ferromagnetic phase transition. Above the Curie temperature (T_C), the spins are randomly oriented and have full rotational symmetry (A). Below T_C , spontaneous symmetry breaking occurs that breaks the rotational symmetry resulting in a macroscopic magnetization (B).

Table 1 Examples of spontaneous symmetry breaking (SSB) in physics including those in solid-state systems and in the standard model.

Phenomenon	Symmetry broken	Observable/manifestation
Ferromagnetism	$SO(3)$	Spontaneous magnetization
Superconductivity	$U(1)$	Zero resistance, Meissner effect
Higgs mechanism	$SU(2) \times U(1)$	Mass of W and Z Bosons
Chiral symmetry breaking in QCD	$SU(3)_L \times SU(3)_R$	Appearance of pions, larger nucleon masses

where θ is the phase associated with the $U(1)$ symmetry (Peskin and Schroeder, 2018). The Lagrangian is then the sum of the familiar kinetic term, and a yet undefined potential, V :

$$\mathcal{L} = \frac{1}{2} \partial_\mu \phi^* \partial^\mu \phi - V(\phi) \quad (2)$$

To write down the potential, we consider the restrictions on its form from both the symmetry of the theory and our desire for a renormalizable theory. First, we cannot have odd powers of ϕ as this would result in an unstable theory (solutions would “roll down” the potential). Additionally, the $U(1)$ global symmetry requirement restricts us to even powers of ϕ . Second, a theory with $\mathcal{O}(\phi^6)$ terms is not renormalizable, limiting us to a square and a quartic term for a simple form. This leads us to the famous “wine bottle” potential:

$$V(\phi) = \frac{\mu}{2} |\phi|^2 + \frac{\lambda}{4} |\phi|^4 \quad (3)$$

where μ and λ are coupling constants. Since the potential must be bounded from below, we require that $\lambda > 0$. However we have no such restrictions on the sign of μ , so we consider the two cases of $\mu > 0$ and $\mu < 0$, with the corresponding potentials illustrated in Fig. 3. For $\mu > 0$, the ground state is unique and the vacuum expectation value (VEV) $\langle \phi_0 \rangle = 0$. In this case both the theory and the unique solution to the theory have $U(1)$ symmetry.

However, an interesting case emerges for $\mu < 0$, as shown in Fig. 3B. Now the scalar potential has a collection of local minima rather than a single unique vacuum. The theory still retains its $U(1)$ symmetry; however, the ground-state solutions to the theory do not. Instead, the vacuum manifold is invariant under $U(1)$ symmetry such that we can transform between these different degenerate vacuum states (the donkey can walk around the base of the potential). This continuum of vacua has amplitude $|\phi_0| = \sqrt{\frac{|\mu|}{\lambda}}$ and can be described as a collection of points on a circle, S^1 . Since the minimum of the potential is not at $|\phi_0| = 0$, symmetry breaking must occur. The process of choosing a particular solution out of these degenerate vacua is *spontaneous*. The order parameter space is the quotient space of $U(1)/1 \simeq U(1)$ which classifies all possible broken-symmetry states.

We next explore what new excitations (if any) are present in the broken-symmetry solution of the vacuum. We do this by picking a vacuum state and examining fluctuations away from the minimum at $|\phi_0| = \sqrt{\frac{|\mu|}{\lambda}}$. Since our collection of vacuum states are invariant under $U(1)$ symmetry, we parametrize the fluctuations around the minimum of our scalar field ϕ in terms of radial and angular contributions:

$$\phi = \frac{1}{\sqrt{2}} \left(h + \sqrt{\frac{-\mu}{\lambda}} \right) e^{i\theta} \quad (4)$$

Here, h and θ are real scalar fields representing the radial and angular fluctuations around the minimum, respectively. Substituting this parameterization into the Lagrangian density, we get:

$$\mathcal{L} = \frac{1}{2} \left(\partial_\mu h \partial^\mu h + \frac{-\mu}{\lambda} \partial_\mu \theta \partial^\mu \theta \right) - \frac{\lambda}{4} h^4 - \frac{1}{2} \mu h^2 + \mathcal{O}(h) \quad (5)$$

First focusing on the angular mode, θ , we find that it is massless, corresponding to the Goldstone mode. This Goldstone mode arises as a consequence of the spontaneous breaking of the $U(1)$ global symmetry and represents the continuous shift in the phase of the complex scalar field ϕ around the minimum of the potential (see Fig. 4). We also see that the radial mode h is massive, with mass $m_h = \sqrt{2|\mu|}$. This will be discussed later and identified as a Higgs mode. In summary, in a $U(1)$ global scalar field theory with a potential of the form given in Eq. (3) where $\mu < 0$, the Goldstone mode arises as a massless excitation corresponding to the phase fluctuation of the complex scalar field. The radial mode corresponds to the massive amplitude fluctuation (Higgs-like particle). The existence of the Goldstone mode is a direct consequence of the spontaneous breaking of the continuous global symmetry.

Although demonstrated here for the straightforward case of SSB in a global $U(1)$ scalar theory, Goldstone’s predictions have broad applicability across a wide range of physical systems that undergo SSB of a continuous symmetry. It is summarized by Goldstone’s Theorem, which states that when a continuous symmetry is spontaneously broken, a corresponding gapless excitation must emerge in the system’s low-energy spectrum (Goldstone, 1961). The excitation is the Goldstone mode and is characterized by

Fig. 3 “Wine bottle” potentials for the form ϕ^4 for (A) $\mu > 0$ and (B) $\mu < 0$. Only (B) exhibits spontaneous symmetry breaking.

Fig. 4 Goldstone (phase) and Higgs (amplitude) modes depicted for a $U(1)$ global theory. The Goldstone modes correspond to fluctuations in angle; Higgs modes correspond to amplitude fluctuations.

its long wavelength and low energy and arises due to the broken symmetry in the system. Furthermore, the theorem predicts that the number of Goldstone modes appearing from the SSB is equal to the number of broken symmetry generators. For the complex scalar field under $U(1)$ global symmetry considered earlier, one broken symmetry (rotational symmetry) resulted in the appearance of one Goldstone mode. Viewed another way, when SSB occurs the symmetry is not completely “broken,” but rather manifests as gapless excitations of the ground state. This allows us to redefine the excitations in the ground state manifold as emergent modes and to use a particular description for their behavior. In more complex systems with multiple broken continuous symmetries, multiple Goldstone modes may emerge, each representing a distinct facet of the broken symmetry with examples given in Table 1.

The emergence of three branches of gapless acoustic phonon modes in a crystalline material is an example of the Goldstone theorem in condensed matter. Crystals are characterized by the spontaneous breaking of translation symmetry—in a three-dimensional crystal there are three generators of translation. The theorem then predicts that these three broken translational symmetries result in the appearance of three gapless modes, corresponding to the three gapless acoustic phonon modes. In general, we expect d branches of gapless (acoustic phonon) modes in a d -dimensional crystal (Nielsen and Chadha, 1976).

One of the most important manifestations of Goldstone modes appears in the theory of the strong nuclear force, as described by quantum chromodynamics (QCD) (Nambu and Jona-Lasinio, 1961; Ryan, 2023). The QCD Lagrangian captures the interaction between quarks and gluons in the Standard Model and exhibits several symmetries, including $SU(3)$ gauge symmetry, chiral, flavor, and isospin symmetry of quarks and baryon number. Of these symmetries, chiral symmetry plays a key role in the appearance of Goldstone modes in QCD. Here, chiral symmetry describes the invariance of the QCD Lagrangian under the separate transformations of left-handed and right-handed components of the quark fields. When chiral symmetry is exact, left- and right-handed components of quarks are indistinguishable. However, the nonzero masses of the quarks only allow for approximate conservation of chiral symmetry. At lower energies, where quarks become strongly coupled, chiral symmetry is spontaneously broken, resulting in the creation of Goldstone bosons called pions. The pion is the lightest meson and plays a crucial role in the behavior of hadrons, the composite particles made up of quarks and gluons. Pions are the Goldstone modes associated with the breaking of chiral symmetry in QCD, and their properties are central in understanding the dynamics of the strong force.

Example: Goldstone modes in the Heisenberg model

We now consider a specific case of SSB and Goldstone modes in condensed matter with the emergence of Goldstone modes in the Heisenberg model. This elegant yet highly informative model describes a cubic lattice of spin- $\frac{1}{2}$ sites interacting via an isotropic exchange interaction:

$$H = -J \sum_{\langle i,j \rangle} \mathbf{S}_i \cdot \mathbf{S}_j \quad (6)$$

where J is the exchange interaction strength and $\mathbf{S}_i = \hbar \boldsymbol{\sigma}_i$ is the spin operator on site i , and $\boldsymbol{\sigma}_i$ are the Pauli matrices. The sites are labeled by i, j , and the sum is taken over all nearest-neighbor pairs. This H is characterized by the orientation of the spins, which can be rotated together without affecting our theory. This gives a net zero expectation value for spin in the absence of symmetry breaking. However, the dot product between nearest-neighbor spins in H , the sign of the exchange interaction, J , dictates the preferred relative orientation of spins in the system. For $J > 0$, the energy is minimized when the spins are parallel, leading to a ferromagnetic ground state. Conversely, when $J < 0$, antialignment of spins is favored, resulting in an antiferromagnetic ground state. These magnetic ground states spontaneously break the rotational symmetry in our theory, and give rise to a gapless Goldstone mode.

To illustrate this concept, let us consider the 1D Heisenberg model with $J > 0$ and explore its low-energy excitations (The general case can be derived of an n -dimensional spin model by performing a Holstein–Primakoff transformation to express H in terms of bosonic creation and annihilation operators.). We rewrite the Hamiltonian in terms of the spin operators $S_i^\pm$:

$$\begin{aligned}
H &= -J \sum_{\langle i,j \rangle} \mathbf{S}_i \cdot \mathbf{S}_j \\
&= -J \sum_{\langle i,j \rangle} S_i^z S_j^z - \frac{1}{2} (S_i^+ S_j^- + S_i^- S_j^+)
\end{aligned} \tag{7}$$

The S_i^+ and S_i^- correspond to the spin raising and lowering operators at site i . Since $J > 0$, the ground state, ϕ_G , corresponds to all spins being aligned:

$$\begin{aligned}
H|\phi_G\rangle &= -J \sum_{\langle i,j \rangle} S_i^z S_j^z |\phi_G\rangle - \frac{J}{2} (S_i^+ S_j^- + S_i^- S_j^+) |\phi_G\rangle \\
&= -J N S^2 |\phi_G\rangle \\
&= E_G |\phi_G\rangle
\end{aligned} \tag{8}$$

To examine low-energy excitations, we rewrite H as linear combinations of states $|i\rangle$ with a single spin flip at site i giving

$$H = \sum_{ij} |i\rangle \langle i| H |j\rangle \langle j| \tag{9}$$

When one spin is flipped, it results in a reversal of two J couplings, at an energy cost of $2JS^2$. Since the interactions are restricted to nearest-neighbor only, all off-diagonal matrix elements vanish except for the nearest-neighbor terms, which lead to the diagonal matrix elements and the nonvanishing off-diagonal terms in Eq. (9). The energy spectrum of these low-energy excitations is then

$$H = (E_G + 2JS^2) \sum_i |i\rangle \langle i| - JS^2 \sum_i (|i+1\rangle \langle i| + |i\rangle \langle i+1|) \tag{10}$$

Taking the Fourier transform of this and diagonalizing the corresponding $H(q)$ we get:

$$E_q = E_G + 2JS^2 [1 - \cos(qa)] \tag{11}$$

The excited state energies in the long wavelength limit ($q \rightarrow 0$) are $\sim Ja^2 q^2$, where a is the lattice spacing and q is the wavenumber. These low-energy excitations are the Goldstone modes associated with the SSB magnetic phase transition, known as magnons. These collective excitations are the magnetic analog of phonons and are generally linear in q for magnetic materials. An exception to this is the ferromagnetic case considered here, which is quadratic in q .

Higgs modes

An alternative description of Goldstone modes is as fluctuations in the phase of the order parameter. For instance, in a conventional superconductor, the continuous $U(1)$ symmetry is spontaneously broken leading to our “wine-bottle” potential with a degenerate circle of minima described by the order parameter $\phi = Ae^{i\theta}$. Fluctuations from the ground state can be classified as transverse Goldstone (phase) modes and longitudinal (amplitude) Higgs modes. Here, the order parameter corresponds to the wave function of Cooper pairs with fluctuations in the phase representing their orientation. In our scalar field theory above, Goldstone modes are the gapless excitations around the bottom of the potential, tracing out a circle. Higgs modes, on the other hand, are characterized by fluctuations of the order parameter around its VEV and are gapped.

We return to the Lagrangian for a $U(1)$ -symmetric complex scalar field Eq. (2) with the potential expressed as:

$$V(\phi) = \frac{\mu}{2} |\phi|^2 + \frac{\lambda}{4} |\phi|^4 \tag{12}$$

By examining fluctuations around the ground-state vacua, we found a radial mode h with mass $m_h = \sqrt{2|\mu|}$, which we identified as a “Higgs”-type excitation. This mode is associated with the amplitude of the scalar field, which means that its excitations correspond to changes in the field’s magnitude. As a result, the Higgs mode plays a fundamental role in defining the energy landscape of the scalar field, as well as the characteristics of the phase where symmetry is spontaneously broken. We see that the Higgs field has acquired a mass *due* to the symmetry breaking, and this is the Higgs mode. Its mass is determined by the Higgs field VEV μ and the coupling strength λ in a $U(1)$ symmetric complex scalar theory.

The Higgs mode was originally theoretically proposed for relativistic theories where the equations of motion have Lorentz symmetry (Higgs, 1964, 1966; Englert and Brout, 1964; Guralnik et al., 1964). In these relativistic theories, the Higgs modes can be well defined and decoupled from Goldstone modes near particle-hole symmetry. Since the presence of Lorentz symmetry imposes constraints on the dispersion relation of the excitations, we then expect the Higgs modes to have a flat dispersion near particle-hole symmetry while Goldstone modes generally have a linear dispersion (Fig. 5). The Higgs’ flat dispersion has important consequences: it implies that the Higgs mode extends over a vast spatial region and possesses minimal energy. Because of this, it can avoid rapid decay into particle-hole pairs. Therefore, particle theories with both Lorentz symmetry and particle-hole symmetry can have observable Higgs modes that are also effectively decoupled from the Goldstone modes.

The observation of Higgs modes is extremely challenging in condensed matter systems for two key reasons (Pekker and Varma, 2015; Podolsky et al., 2011). First, particle-hole symmetry is required to fully decouple the Goldstone and Higgs modes to avoid their rapid decay into other excitations. In such systems, the Fermi level is located at the center of the energy gap, and the electron

Fig. 5 A schematic excitation spectrum of an *s*-wave superconductor. Due to the Anderson–Higgs mechanism, the Nambu–Goldstone mode acquires an energy gap in the order of the plasma frequency ω_p while the Higgs mode remains in low energy with an energy gap 2Δ , above which the quasiparticle excitation continuum overlaps.

and hole states are degenerate in energy. Careful tuning of the chemical potential in systems ranging from trapped atoms and uniaxial antiferromagnets to superconductors can achieve approximate particle-hole symmetry allowing for the detection of Higgs modes in principle. In particular the search for Higgs modes in superconductors is appealing since they are particle-hole symmetric at low energies surrounding the superconducting gap.

The second, perhaps more fundamental, challenge for the detection of Higgs modes in solid-state systems relates to its scalar nature. In condensed matter systems, the Higgs mode is a scalar, lacking charge, spin, or any other distinguishable quantum number, making it “dark” to conventional experimental probes that linearly couple to quantum numbers. Therefore observation of the Higgs mode in condensed matter systems relies on indirect probes requiring nonlinear couplings to conventional states in quantum matter or on rapid nonequilibrium probes of the system (Shimano and Tsuji, 2020).

In the quest to observe the elusive Higgs mode, a promising proposal involves examining spectral weight redistribution between the Higgs mode and optical phonons in superconductors. This can be observed in low-temperature Raman spectroscopy in close proximity to the superconducting transition temperature (T_C). When Raman active modes couple with Higgs mode, a shift in spectral weight occurs which can be identified as a pole in the self-energy of the Raman-active phonon. This results in two resonances with an aggregate weight equal to the single resonance above the superconducting transition temperature.

The conservation of total spectral weight emerges naturally when the Higgs mode is linearly coupled to Raman active optical phonons. However, this coupling seems to violate particle number conservation while conserving charge conservation. In principle, this can be allowed if lattice vibrations only couple with electronic charge density. In this scenario, the Higgs mode can be observed through a process in which the lattice vibration “shakes” the condensate and generates a particle-number nonconserving condensate (Littlewood and Varma, 1982).

Recent experimental advancements in Raman scattering on metals have successfully detected spectral weight transfer which can be attributed to the Higgs mode (Méasson et al., 2014). When Higgs-phonon coupling is present, the combined spectral weight of the two resonances below the superconducting transition temperature is predicted to equal the weight of a single resonance above it. Investigations using Raman spectroscopy on NbSe₂ in both normal and superconducting states have revealed optical phonons at 2 K and above the superconducting transition ($T_C = 7.2$ K). Furthermore, an additional peak emerges at roughly twice the superconducting gap or 2Δ . This conservation of spectral weight in each channel provides compelling evidence for the vertex responsible for coupling the Higgs mode; however, other possible causes of these resonances have also been proposed (Balseiro and Falicov, 1980).

A direct coupling of the Higgs mode to experimental probes can in principle be achieved using the Josephson effect. By coupling two superconductors with the same symmetries but different amplitudes, one can drive both Goldstone and Higgs mode by applying a time-dependent voltage. This was used in experiments near T_C by Carlson and Goldman and Kadin and Goldman, who identified a new set of phase modes, known as the Carlson–Goldman modes (Carlson and Goldman, 1975; Kadin and Goldman, 1982). However, despite these observations, the corresponding amplitude modes (Higgs modes) have yet to be observed using this technique.

Ongoing research in the field of superconductivity has revealed that more complex scenarios with multiple Higgs modes are possible, potentially shedding light on open questions about the nature of superconductivity. Superfluid ³He, which possesses a multicomponent order parameter, displays various collective oscillation modes between the different components of the order parameter (Vollhardt and Wolfe, 2013). In the case of cuprate superconductors, a mysterious mode has been observed directly in Raman scattering at an energy of approximately 1.5Δ , where Δ is the maximum gap. This mode has been identified as the amplitude mode of the superconductor, which is suggested to draw spectral weight from the continuum in a similar coupling mechanism to the Higgs-phonon scenario described above (Katsumi et al., 2018). It has also been suggested that non-*s*-wave order parameters can give rise to multiple symmetry-dependent Higgs modes, leading to a complex superconducting state with several competing mechanisms. These findings highlight the importance of understanding the appearance and control of Higgs modes in quantum materials with complex order parameters spaces such as high- T_C superconductors (Schwarz et al., 2020).

Higgs mechanism

The SSB cases we have explored in detail to now have focused on the spontaneous breaking of a global symmetry which we show via Goldstone's Theorem results in the creation of a massless Goldstone boson. However, when a local (gauge) symmetry instead is broken, the Goldstone bosons are “eaten” by the gauge bosons, giving them mass and leaving no massless Goldstone bosons in the resulting theory. This process is commonly known as the Higgs mechanism (Several papers published in close succession proposed a mechanism whereby massless Goldstone bosons interact with massless gauge bosons to produce a massive vector mode. This motivates the more complete title—the Anderson-Brout-Englert-Guralnik-Hagen-Kibble-Higgs phenomenon.), and it plays a pivotal role in the electroweak symmetry breaking that gives mass to the W and Z bosons, which are responsible for mediating the weak nuclear force.

Example: Higgs mechanism

We first derive the Higgs mechanism for an explicit theory to demonstrate how it imbues mass on otherwise massless particles. Following this, we will discuss the importance of the Higgs mechanism for understanding particles in condensed matter and in high-energy physics. We begin with our previous $U(1)$ complex scalar theory, but now couple it to electromagnetism. This results in an abelian $U(1)$ gauge theory:

$$\mathcal{L} = (D_\mu \phi)^\dagger (D^\mu \phi) - V(\phi) - \frac{1}{4} F_{\mu\nu} F^{\mu\nu} \quad (13)$$

Where $D_\mu = \partial_\mu + ieA_\mu$ is the covariant derivative, e is the gauge coupling constant, $V(\phi)$ is a Higgs potential, and $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ is the field strength tensor for the $U(1)$ gauge field. We choose a Higgs potential with SSB, such as the “wine bottle” potential in Eq. (12). Since the minimum of the potential is not at $\phi_0 = 0$, SSB occurs. Again we can parameterize the complex scalar field ϕ in terms of the radial and angular fluctuations around the minimum, respectively. Substituting this parameterization into the Lagrangian density, we get:

$$\mathcal{L} = \frac{1}{2} (\partial_\mu h)^2 + \frac{1}{2} \left(h + \sqrt{\frac{-\mu}{\lambda}} \right)^2 (\partial_\mu \theta - eA_\mu)^2 - V(h) - \frac{1}{4} F_{\mu\nu} F^{\mu\nu} \quad (14)$$

In this expression, the gauge field A_μ acquires a mass term proportional to $(h + \sqrt{\frac{-\mu}{\lambda}})^2$. The mass of the gauge boson is given by:

$$m_A = e \sqrt{\frac{-\mu}{\lambda}} \quad (15)$$

The radial mode h is massive, while the angular mode θ is “eaten” by the gauge field through the Higgs mechanism, providing the gauge boson with mass. In this case, the massless Goldstone mode associated with the phase fluctuation does not manifest as a separate physical excitation. The scalar field's angular mode, θ , becomes part of the longitudinal degree of freedom of the now massive gauge boson, and the Goldstone mode disappears as an independent excitation.

The Higgs mechanism and the concept of SSB are essential components of our current understanding of fundamental particles and their interactions. It predicts how a massive boson can be created when massless Goldstone modes combine with gauge bosons upon SSB, and is generally applicable in both nonrelativistic and relativistic theories. These descriptions and mechanisms are broadly applied across the landscape of physics ranging from condensed matter and particle physics to cosmology, where they help explain the emergence of various ordered states and phase transitions.

In particle physics, the Abelian Higgs mechanism described above can be extended to non-Abelian gauge theories, such as the $SU(2) \times U(1)$ electroweak gauge theory, which is a cornerstone of the Standard Model of particle physics. In the electroweak theory, the Higgs mechanism is responsible for giving mass to the W and Z bosons, which mediate the weak nuclear force, as well as providing masses to the quarks and charged leptons through Yukawa interactions with the Higgs field. In the context of Standard Model, SSB of the electroweak gauge theory creates a massive scalar particle—the Higgs boson—which give mass to other Standard Model particles. The discovery of the Higgs boson with a mass of ~ 125 GeV at CERN in 2012 validated the Higgs mechanism and existence of the Higgs field.

The Higgs mechanism plays a key role in the theoretical understanding of superconductors, and was in fact originally proposed in the context of superconductors by Anderson (and is often dubbed the Anderson-Higgs mechanism because of this) (Anderson, 1963). Superconductors undergo a phase transition from the normal conducting state to the superconducting state below a critical temperature, which is characterized by the onset of a Cooper pair condensate. This phase transition is described as the spontaneous breaking of the $U(1)$ gauge symmetry associated with electromagnetism. The interplay between the SSB and the breaking of a gauge symmetry result in the massless gauge boson (the photon in this case) acquiring mass. Therefore the effective mass of photons within the superconductor increases because of their interaction with the Cooper pair condensate. The appearance of this massive gauge boson leads to the Meissner effect, where magnetic fields are expelled from the bulk of a superconductor.

Topological phases and emergent quasiparticles

While SSB plays a key role in the appearance of Goldstone and Higgs modes, it can also lead to other particle-like phenomena. A particular interesting class of SSB-induced phenomena is the emergence of topological defects (TDs) that are determined by the system's topology. TDs emerge in regions where a continuous symmetry is broken, giving rise to nontrivial configurations that cannot be locally rearranged (Griffin and Spaldin, 2017). The stability of TDs against local deformations stems from the global characteristics of the order parameter, which are inherently embedded in its topology. TDs occur when the SSB of a continuous symmetry in a system also corresponds to a change in the homotopy group during a phase transition (Kibble, 1976). While Goldstone modes represent massless fluctuations around a vacuum that are caused by SSB, TDs originate from distinct choices of local configurations within the order parameter field. This leads to the formation of various phenomena, including vortices in superfluids, dislocations in crystalline solids, and topological solitons such as domain walls and skyrmions in magnetic materials.

Originally proposed in the context of nuclear physics, skyrmions are TDs that emerge in ferroic systems. They are solitonic solutions to the relevant effective theory that have a twist or kink the order parameter field that cannot be removed. As emergent quasiparticles, skyrmions display particle-like attributes, such as individual mobility, mutual interactions, and the ability to act collectively. TDs can also act to induce and localize physics that does not appear in a bulk system. For instance, the appearance of Majorana fermions in topological superconductors is predicted to occur at one-dimensional TDs or vortices. Majoranas are quasiparticles that act as their own antiparticles and are the key building block for topological quantum computing. Finally, the effective description of TDs can be mapped onto other models of emergent quasiparticles such as the magnetic behavior in “spin ice” and the emergent magnetic monopoles that appear (Bramwell et al., 2009).

The interplay between TDs and emergent quasiparticles opens up a rich and complex phase space where new, exotic quasiparticles can appear. Studying these connections can provide valuable insights into the emergent behavior of many-body systems and unveil new possibilities for the manipulation and control of their properties. Understanding these interactions also allows us to manipulate and control the properties of these systems more effectively. For instance, through various physical and chemical methods like applying fields or doping, we can refine the systems for optimal performance.

Dark matter detection

Standard Model matter described above constitute only 25% of the matter mass in the universe; the rest is dubbed “dark” as it does not couple to electromagnetism. There is an increasing litany of indirect evidence for DM ranging from Vera Rubin's observations of the rotational curves of galaxies to gravitational lensing and structure in the cosmic microwave background. These all suggest that there is significantly more matter in the universe that cannot be accounted for by Standard Model matter. However, despite the wealth of indirect evidence for DM, so far it has evaded direct detection making it one of the biggest open questions in modern physics.

Current evidence for DM suggests that it makes up the majority of matter in the universe, inferred from the “missing” matter that is needed to account for existing observations. However, this evidence does not give us information on the mass of individual DM particles/waves. Because of this, the search for DM must extend across a vast range of magnitudes, from massive galactic objects like black holes to subatomic particles and wave-like phenomena. Among the most promising DM candidates are weakly interacting massive particles (WIMPs), with masses ranging from $10 \text{ GeV}/c^2$ to $10 \text{ TeV}/c^2$ down to lighter “wave-like” modes of DM, such as the axion, are theorized to have masses in the range of 10^{-22} – $10^{-6} \text{ eV}/c^2$.

Direct detection experiments commonly seek to detect DM through their interaction with our known matter that is described by Standard model. For instance, particle-like DM, since it has mass, has well-defined momentum and kinetic energy and so can scatter from DM particles, given the right kinematic constraints. This principle is used in the current searches for WIMPs which look for DM-induced recoil of nuclei in large volumes of target materials. Yet, despite significant effort, these searches have yet to uncover definitive evidence of DM, and so new strategies are needed to expand the parameter space in the search for DM. One promising approach involves the use of more sensitive detection schemes capable of detecting lower-mass DM than many of the existing searches. However, this requires a rethinking of the experimental and sensing setup to make it sensitive to DM masses lower than the WIMP scale (Essig, 2020). One potential avenue is to explore collective excitations in quantum materials such as phonons, electrons, and magnons as scattering targets for such low-mass DM (see Fig. 6).

Condensed matter physics provides valuable insights and techniques for the detection of DM. For example, cryogenic detectors for studying condensed matter systems, such as superconductors, has led to the development of similar detectors for DM searches. These detectors rely on the detection of tiny amounts of energy released when DM particles scatter off of the detector material, which can be measured using sensitive electronics. In addition, condensed matter physics has also contributed to the development of new materials and technologies that can enhance the sensitivity of DM detectors. For example, the use of superconducting materials can allow for the detection of smaller energy signals from DM interactions while the use of quantum-enhanced sensing can potentially improve signal-to-noise ratios, which are key for these highly sensitive searches.

Fig. 6 Projected reach for dark photon-mediated dark matter (DM) scattering via Dirac electron and single phonon excitations with 1 kg-year exposure and no background. For the Dirac electron case, the sensitivity is shown for ZrTe_5 (Hochberg et al., 2018) while for the single phonon case, the sensitivity is shown for H_2O with a 20 meV detector threshold (Taufertshöfer et al., 2023). Existing constraints and other proposed experiments are included for comparison.

Conclusion

SSB and its role in describing matter in the form of quasiparticle excitations pervades all areas of physics ranging from the micro- to macroscopic. The common description of collective excitations across high-energy physics and condensed matter has served as an important bridge in connecting the communities. This unity has paved the way for groundbreaking discoveries, such as superconductivity and the discovery of the Higgs boson. As more complex manifestations and interactions of these collective excitations emerge, the need for comprehensive theoretical descriptions and novel measurement probes will maintain the search and understanding for new quasiparticles as an exciting and vibrant area of research.

Abstract

Some important rigorous results on phase transitions accompanied by the spontaneous breaking of symmetries in statistical mechanics and relativistic quantum field theory are reviewed. Basic ideas, mainly inspired by quantum field theory, underlying the proofs of some of these results are sketched. The Goldstone theorem is proven, and the Mermin–Wagner–Hohenberg theorem concerning the absence of continuous symmetry breaking in one and two dimensions is recalled. Comments concerning rigorous results on the Kosterlitz–Thouless transition in the two-dimensional classical XY model are made.

Key points

- A heuristic introduction to the subject of spontaneous symmetry breaking, Goldstone's theorem and the Anderson–Higgs mechanism in the context of quantum field theory is given. The Wick rotation from real to imaginary time and the equivalence of real-time relativistic quantum field theory (RQFT) and imaginary-time Euclidean field theory (EFT) are recalled.
- The $\lambda|\phi|^4$ -Euclidean field theory of a real or complex scalar field ϕ in three dimensions is introduced. Its relevance for understanding various systems of statistical mechanics and condensed matter physics, for example, Bose gases, is commented upon. It is shown that the broken-symmetry phase of the theory of a complex field exhibits massless modes, in accordance with the Goldstone theorem.
- A general proof of the Goldstone theorem in the formalism of EFT is presented. The example of $\lambda|\phi|^4$ -theory of a complex scalar field in three dimensions is considered in more detail. Bounds on critical exponents for the susceptibility of the theory and its correlation length, as phase transition points in zero magnetic field are approached, are reviewed.
- A summary of results on phase transitions accompanied by spontaneous symmetry breaking for classical and quantum (lattice) spin systems is presented. The role of “Reflection Positivity” and “Infrared Bounds” in the analysis of phase transitions is emphasized. For the classical XY model, the usefulness of a representation as a vortex gas for the analysis of the massless low-temperature phase and for the analysis of the Kosterlitz–Thouless transition is indicated.

Introduction to spontaneous symmetry breaking and the Higgs mechanism

This contribution is **not** an exhaustive review of the subject of spontaneous breaking of (continuous) symmetries or its absence, the Goldstone theorem, the Mermin–Wagner–Hohenberg theorem, the Anderson–Higgs mechanism, etc. My modest goal is to provoke the readers' interest in this subject, to draw attention to the fruitful intertwining between statistical mechanics and particle physics, in particular quantum field theory, and to draw some attention to the more mathematical literature on these matters. I will not state the relevant results in all detail, let alone describe proofs. For further information, the readers are invited to consult the papers quoted in the text.

Phase transitions in systems of condensed matter have been studied ever since the 19th century, using the formalism of thermodynamics, by *Clausius*, *Clapeyron*, *Maxwell*, *Gibbs* and others. Their findings are well known and are taught in every introductory course on the theory of heat. Toward the end of the 19th and at the beginning of the 20th century, statistical mechanics was created by *Maxwell*, *Boltzmann*, *Gibbs*, and *Einstein*. The first example of a phase transition accompanied by the breaking of a continuous symmetry, treated by using the methods of equilibrium statistical mechanics, was *Bose–Einstein*

condensation exhibited by ideal Bose gases when the temperature is lowered at some fixed positive density. Further examples relevant for the description of liquid–gas transitions and anisotropic magnetism, mostly with discrete symmetries, were studied subsequently. A famous model in this context is the Ising model. The phenomena of superconductivity and ferromagnetism inspired many further efforts to understand phase transitions, spontaneous symmetry breaking, and critical phenomena near continuous transitions. It is not the purpose of this contribution to provide a detailed overview on this field. General surveys of equilibrium statistical mechanics, including the theory of phase transitions, can be found in the monographs (Ruelle, 1969; Bratteli and Robinson, 1979, 1981; Simon, 1993), which are written in the style of mathematical physics. Rich sources of results on continuous phase transitions, symmetry breaking and critical phenomena are Domb and Green (1972–1976), Domb and Lebowitz (1983–2001), and Itzykson and Drouffe (1989). Phase transitions accompanied by spontaneous symmetry breaking and the Anderson–Higgs mechanism later came to play a fundamental role in particle physics; see Weinberg (1995–2000) and references given there. As already mentioned, a very attractive feature of this subject is that it is a great example of productive interactions between statistical and condensed matter physics, on one hand, and particle physics and quantum field theory, on the other hand.

I begin my tale by briefly recalling the heuristics of spontaneous symmetry breaking and the Anderson–Higgs mechanism in relativistic quantum field theory (RQFT). The simplest theory is one of a complex scalar field ϕ , which I write in polar coordinates

$$\phi(x) = e^{i\theta(x)} \rho(x), \quad x \in \mathbb{M}^4, \quad (1)$$

where $\theta(x) \in [0, 2\pi)$ is the azimuthal angular variable and $\rho(x) \equiv |\phi(x)| \in [0, \infty)$ is the radial variable, for every space-time point x in Minkowski space $\mathbb{M}^4$. The symmetry group of the theory is $U(1)$. In order to distinguish spontaneous symmetry breaking from the Anderson–Higgs mechanism, I couple ϕ to a $U(1)$ -gauge field/connection, A_μ , with $\mu = 0, 1, 2, 3$. In studies of superconductivity this gauge field is the electromagnetic four-vector potential. A typical action functional for the fields ϕ and A_μ has the form

$$S(\phi, A_\mu) = \frac{1}{2} \int d^4x \{ [\partial_\mu + ieA_\mu(x)] \bar{\phi}(x) \cdot [\partial^\mu - ieA^\mu(x)] \phi(x) - U(|\phi(x)|) \}, \quad (2)$$

where e is the gauge charge (i.e., twice the elementary electric charge, in the case of superconductivity) and $U(|\phi|)$ is the self-interaction potential for the scalar field, which is assumed to be invariant under the transformation $\phi \mapsto e^{i\theta_0} \phi$, where $e^{i\theta_0}$ belongs to the symmetry group $U(1)$. If ϕ is written in polar coordinates, $S(\phi, A_\mu)$ takes the form

$$S(\phi, A_\mu) = \frac{1}{2} \int d^4x \{ \rho(x)^2 [\partial_\mu \theta(x) - eA_\mu(x)] \cdot [\partial^\mu \theta(x) - eA^\mu(x)] + \partial_\mu \rho(x) \cdot \partial^\mu \rho(x) - U(\rho(x)) \}. \quad (3)$$

I assume that the self-interaction potential $U(\rho)$ is nonnegative and has the shape of a Mexican hat, with a sharp minimum at $\rho = R > 0$ (so that $\rho(x)^2 \approx R^2$).

One distinguishes the following two situations.

1. *Continuous symmetry breaking with Goldstone bosons:* We set $e = 0$, so that the gauge field is absent, and write $S(\phi)$ instead of $S(\phi, A_\mu)$. Then

$$S(\phi) \simeq S_1(\theta) + S_2(\rho), \quad \text{where} \quad (4)$$

$$S_1(\theta) = (R^2/2) \int d^4x \partial_\mu \theta \cdot \partial^\mu \theta,$$

$$S_2(\rho) = \frac{1}{2} \int d^4x \{ \partial_\mu \rho \cdot \partial^\mu \rho - U(\rho) \}, \quad (5)$$

and the vacuum expectation value of ϕ in a pure vacuum state, $|\emptyset\rangle_{\theta_0} \equiv |\emptyset\rangle$, can be expected to be given by

$$\langle \emptyset | \phi | \emptyset \rangle \approx e^{i\theta_0} R \neq 0, \quad \text{for some } \theta_0 \in [0, 2\pi).$$

The fact that $\langle \emptyset | \phi | \emptyset \rangle \neq 0$ and the appearance of the angular parameter θ_0 are a signal of spontaneous symmetry breaking. Expression (4) shows that the modes described by the angular field θ are massless—these are the modes describing the Goldstone bosons that accompany spontaneous symmetry breaking—while the fluctuations of the radial modes described by the field ρ around the minimum of U at $\rho = R$ may seem to be massive, assuming that the curvature of $U(\rho)$ at $\rho = R$ is positive. Actually, these modes are unstable and decay into pairs of Goldstone bosons. This can be understood by expanding the self-interaction potential $U(|\phi|)$ around one of its minima and then noticing that the fluctuations of the radial field ρ couple to pairs of Goldstone bosons. There is a rigorous result confirming this claim (see Dunlop and Newman, 1975).

Note that, for a theory in *two* space-time dimensions, the form of the action functional (4) suggests that the fluctuations of the angular field θ diverge in the infrared, which implies that there is no spontaneous symmetry breaking. This is the content of the Mermin–Wagner–Hohenberg (–Coleman) theorem. Continuous symmetries can only be broken in space-times of dimension ≥ 3 .

2. *Anderson–Higgs mechanism*: The gauge charge e does *not* vanish, and A_μ is a dynamical gauge field, with a gauge-field action given by

$$S_0(A_\mu) = \frac{1}{4} \int d^4x F_{\mu\nu} \cdot F^{\mu\nu}.$$

We may then set

$$\hat{A}_\mu := A_\mu - e^{-1} \partial_\mu \theta.$$

Obviously, the vector potential $\hat{A}_\mu$ is gauge-equivalent to A_μ . We observe that the angular field θ can be eliminated from the theory by a gauge transformation, and the action $S(\phi, A_\mu)$ becomes

$$S(\rho, A_\mu) \simeq \frac{1}{4} \int d^4x \left\{ \hat{F}_{\mu\nu} \cdot \hat{F}^{\mu\nu} + 2e^2 R^2 \hat{A}_\mu \hat{A}^\mu \right\} + S_2(\rho),$$

where we have used that $\hat{F}_{\mu\nu} = F_{\mu\nu}$ (by gauge invariance).

We observe that the gauge field $\hat{A}$ is **massive**, with a mass proportional to eR , and the radial modes described by ρ remain present and are massive; these modes are the ones that describe the Higgs bosons. Actually, Higgs bosons are usually unstable particles—resonances—that decay into lighter particles, which the field ρ couples to.

Spontaneous symmetry breaking has first been studied, quite a long time ago, for example in the theory of ferromagnetism (Weiss, 1907; Renker, 1913; Heisenberg, 1928) and, in particle physics, in the celebrated work of Nambu and Jona-Lasinio (1961a, b). The fact that the spontaneous breaking of a continuous symmetry is accompanied by the emergence of massless scalar or pseudo-scalar bosons is the content of the Goldstone theorem (Goldstone, 1961; Goldstone et al., 1962).

The arguments leading up to the Higgs mechanism described in item 2 go back, originally, to work by Stückelberg (1938a, b, c) and Anderson (1962). In particle physics, the Higgs mechanism was then studied by Englert and Brout (1964), Higgs (1964), and Guralnik et al. (1964). The Higgs mechanism also works for *non-Abelian gauge fields*, which is relevant for the Standard Model of Particle Physics. The renormalizability of non-Abelian gauge fields coupled to Higgs scalars has first been analyzed in 'tHooft and Veltman (1972), and in Lee and Zinn-Justin (1972a, b, c).

If the scalar field ϕ is coupled to a dynamical gauge field A_μ , then it does not make sense to speak of spontaneous symmetry breaking. The vacuum expectation value of ϕ vanishes unless a special gauge is chosen, in which case it can be given an arbitrary value that is irrelevant for the physical properties of the theory. A manifestly gauge-invariant formulation of the Higgs mechanism (not involving any artificial assumptions concerning the vacuum expectation value of the Higgs scalar ϕ) has been given in Fröhlich et al. (1981).

The following survey is limited to the mathematical theory of spontaneous symmetry breaking, the Goldstone theorem and the Mermin–Wagner–Hohenberg theorem in the context of statistical mechanics and condensed matter physics. I do not pursue the study of the Higgs mechanism; but see, for example, Weinberg (1995–2000).

If a Wick rotation to imaginary time is performed on an RQFT, one obtains what is called a *Euclidean field theory* (EFT). It has been shown by Osterwalder and Schrader (1975) (see also Glaser, 1974) that from the Euclidean Green functions, also called Schwinger functions, of an EFT satisfying *Reflection Positivity* (which is a manifestation of unitarity at imaginary time) one can reconstruct the vacuum expectation values of products of the relativistic (real-time) fields of a corresponding RQFT. EFT's of scalar fields can be viewed as systems of statistical mechanics in a state of thermal equilibrium, as first understood by Schwinger, Symanzik, and Nelson; see Simon (1974), Glimm and Jaffe (1981), and references given there. For classical and quantum lattice systems, Reflection Positivity expresses the self-adjointness of the transfer matrix of the system in question and gives rise to a variety of crucial bounds on numerous physical quantities. It plays a central role in many studies of phase transitions and symmetry breaking in EFT and in important models of classical and quantum lattice systems, as indicated below.

After a sketch of how the phase transition accompanied by continuous symmetry breaking is treated in a concrete example of EFT, namely $\lambda|\phi|^4$ -theory in three dimensions (see Section “The phase transition in the $\lambda|\phi|^4$ -Euclidean field theory in three dimensions”), I will present a proof of the Goldstone theorem in the formalism of EFT (Section “Proof of the Goldstone theorem for Euclidean field theories”) and outline consequences for $\lambda|\phi|^4$ -theory in three dimensions (Section “The example of $\lambda|\phi|^4$ -theory”). In Section “Phase transitions and symmetry breaking in classical and quantum lattice systems,” I focus attention on systems of classical and quantum statistical mechanics in states of thermal equilibrium, and I will summarize some important results for lattice theories; see also Fröhlich (1978, 2011) for more detailed surveys.

The phase transition in the $\lambda|\phi|^4$ -Euclidean field theory in three dimensions

The analysis of the phase transition in $\lambda|\phi|^4$ -theory in three dimensions presented in this section follows the original work reported in Fröhlich et al. (1976).

Henceforth I will always assume that the Wick rotation to purely imaginary time has been made (see Jost, 1965; Osterwalder and Schrader, 1975), and I will thus only consider Euclidean field theories. Such theories are equivalent to classical Hamiltonian systems

in a state of thermal equilibrium. In this interpretation, the Euclidean action functional becomes the Hamilton functional of the classical system. I will focus my attention on $\lambda|\phi|^4$ -theory at imaginary time.

The Euclidean action functional of $\lambda|\phi|^4$ -theory is given by

$$S_\Lambda(\phi) := \int_\Lambda d^3x \left\{ \frac{1}{2} |\nabla \phi(x)|^2 + U(|\phi(x)|) + c.t. \right\}, \quad \text{with} \quad (6)$$

$$U(|\phi|) = \frac{\lambda}{4!} [|\phi|^2 - R^2]^2 - h\varphi^1,$$

where $\phi = (\varphi^1, \dots, \varphi^N)$ is a scalar field with $N = 1, 2, \dots$ real-valued components (equivalent to a complex scalar field, for $N = 2$), Λ is a cube in $\mathbb{R}^3$ with sides of length L and with periodic boundary conditions imposed at the boundary $\partial\Lambda$, “c.t.” stands for a logarithmically divergent mass counterterm, $\delta m^2(\lambda) |\phi|^2$ (with $\delta m^2(\lambda) \propto \lambda^2$), and a divergent (c-number) vacuum-energy counterterm, $\lambda > 0$ is a coupling constant (not renormalized in the three-dimensional theory), R^2 is a real parameter tuning the location of the minima of U in field space and thereby driving a phase transition accompanied by spontaneous symmetry breaking, and $h \geq 0$ plays the role of a small symmetry breaking “magnetic field” in the 1-direction in field space.

We note that, for $h = 0$, the $\lambda|\phi|^4$ -theory with action functional as given in (6) has a global $O(N)$ symmetry (with $O(1) = \mathbb{Z}_2$). The theory is of obvious physical interest. For $N = 1$, it is expected to have the same critical properties as the three-dimensional Ising model, thus describing critical phenomena encountered in liquid-gas transitions. Next, we consider the theory of a complex scalar field equivalent to the theory of a field with $N = 2$ real scalar components.

- This theory turns out to describe the “mean-field limit” of translation-invariant Bose gases with repulsive two-body interactions of very short range (approaching δ -function interactions); see, for example, Fröhlich et al. (2020, 2023). The fact that $\lambda|\phi|^4$ -theory undergoes a phase transition accompanied by spontaneous symmetry breaking, the proof of which is sketched below, is an indication that Bose gases with weak repulsive two-body interactions of short range exhibit Bose–Einstein condensation, as the temperature is lowered at some fixed positive density—a conjecture/claim whose mathematical proof has remained elusive, so far.
- The critical phenomena observed near the point in parameter space where $\lambda|\phi|^4$ -theory with $N = 2$ real scalar fields undergoes a continuous phase transition are expected to be identical to those observed for the classical XY-model (rotator) and to be relevant for understanding critical phenomena exhibited by superfluid Helium, to mention an example. Moreover, for $N = 3$, the theory is expected to describe critical phenomena observed in three-dimensional ferromagnets near their critical point. See Domb and Green (1972–1976), Domb and Lebowitz (1983–2001), and references given there.

In $d = 3$ dimensions, $\lambda|\phi|^4$ -theory with an action functional given by (6) is a superrenormalizable theory that can be constructed nonperturbatively by using functional integration. There are no field strength and coupling constant renormalizations. It makes perfect mathematical sense! The control of ultraviolet divergences of the theory was first accomplished in Glimm and Jaffe (1973), the infinite-volume limit, $L \rightarrow \infty$, was shown to exist in Feldman and Osterwalder (1975, 1977) and Park (1977); see also Glimm and Jaffe (1981) and Brydges et al. (1983).

In the following, we consider the theory in the infinite-volume (“thermodynamic”) limit $L \rightarrow \infty$, unless stated otherwise. If $\lambda = 0$ (and $L = \infty$) the theory is determined by the free-field Gaussian measure of mean 0 and covariance $\delta^{ij}(-\Delta)^{-1}$ defined on a space of $\mathbb{R}^N$ -valued tempered distributions, $\mathcal{S}'(\mathbb{R}^3)^{\times N}$; (Δ is the three-dimensional Laplacian). The Euclidean one-point and two-point Green functions, that is, the first and second moments of the free-field Gaussian measure, are given by

$$\langle \varphi^j(x) \rangle_0 \equiv 0, \quad \text{and} \quad \langle \varphi^i(x) \varphi^j(y) \rangle_0 = \frac{\delta^{ij}}{4\pi|x-y|}. \quad (7)$$

The two-point function, $\langle \varphi^i(x) \varphi^j(y) \rangle_0$, is given by the Green function of the Laplacian Δ , for all $i = 1, \dots, N$. In the following, $:(\cdot):$ indicates standard Wick ordering with respect to the massless free field introduced in (7); for example,

$$:\varphi^i(x) \varphi^j(y): = \varphi^i(x) \varphi^j(y) - \frac{\delta^{ij}}{4\pi|x-y|}.$$

We rewrite the contribution of the self-interaction potential $U(|\phi|)$ to the action functional S_Λ as follows:

$$\begin{aligned} U_\Lambda(R^2, h; |\phi|) &:= \int_\Lambda d^3x \left[: U(|\phi(x)|) : - \frac{\lambda R^4}{4!} \right] \\ &= \int_\Lambda d^3x \left\{ \lambda : |\phi(x)|^4 : - \frac{\lambda R^2}{12} : |\phi(x)|^2 : - h\varphi^1(x) \right\} \\ &= U_\Lambda(0, h; |\phi|) - \frac{\lambda R^2}{12} \int_\Lambda d^3x : |\phi(x)|^2 :. \end{aligned} \quad (8)$$

We then define the “partition function” of the theory by

$$Z_\Lambda(R^2, h) := Z_\Lambda(0, 0)^{-1} \int \mathcal{D}\phi \exp \left[-\frac{1}{2} \int_\Lambda d^3x |\nabla \phi(x)|^2 + \frac{\lambda R^2}{6} : |\phi(x)|^2 : + c.t. \right] e^{-U_\Lambda(0, h; |\phi|)}, \quad (9)$$

and the “free energy” as

$$F(R^2, h) := \lim_{L \rightarrow \infty} L^{-3} \ln Z_\Lambda(R^2, h). \quad (10)$$

The functional integral in (9) can be given a precise mathematical meaning (see [Glimm and Jaffe \(1981\)](#) and references given there). Expectation values with respect to the normalized functional measure appearing under the integral of the right side of (9) are denoted by $\langle (\cdot) \rangle_{R,h}$. The following properties of the function $F(R^2, h)$ are known.

I. $F(R^2, h)$ is a convex function of R^2 , with

$$\frac{\lambda}{12} \langle : |\phi(0)|^2 : \rangle_{R,h} = \frac{\partial F(R^2, h)}{\partial R^2} \nearrow \infty, \quad \text{as } R^2 \rightarrow +\infty. \quad (11)$$

II. For fields ϕ with $N = 1, 2, 3$ components, the function $F(R^2, h)$ is analytic in h away from the imaginary axis. This is a consequence of a generalized Lee–Yang theorem; see [Lee and Yang \(1952\)](#), [Simon and Griffiths \(1973\)](#), and [Dunlop and Newman \(1975\)](#).

These statements and the following analysis of the phase transition in $\lambda|\phi|^4$ -theory in three dimensions are discussed in detail in [Fröhlich et al. \(1976\)](#).

From (11) it follows that, given a finite constant $M^2 > 0$, there exists a constant $R_M^2 < \infty$ such that

$$\langle : |\phi(0)|^2 : \rangle_{R,h} \geq M^2 > 0, \quad \text{for } R^2 \geq R_M^2 \text{ and all } h \geq 0. \quad (12)$$

Next we note that

$$\begin{aligned} \langle : |\phi(0)|^2 : \rangle_{R,h} &= \lim_{y \rightarrow 0} \left\{ \langle \phi(y) \cdot \phi(0) \rangle_{R,h} - \frac{N}{4\pi|y|} \right\} \\ &= \lim_{y \rightarrow 0} \left\{ \langle \phi(y) \cdot \phi(0) \rangle_{R,h}^c + \langle \varphi^1(0) \rangle_{R,h}^2 - \frac{N}{4\pi|y|} \right\}. \end{aligned} \quad (13)$$

Here $\langle (\cdot) \rangle_{R,h}^c$ stands for “connected (truncated) expectation values.” Since the “magnetic field” h only couples to φ^1 , we have that $\langle \varphi^i(0) \rangle_{R,h} = 0$, for $i = 2, \dots, N$, by symmetry, but that

$$\langle \varphi^1(0) \rangle_{R,h} \geq 0, \quad \text{for } h \geq 0. \quad (14)$$

In fact, $\langle \varphi^1(0) \rangle_{R,h}$ is an increasing function of h on the positive half-axis, as follows from the fact that the connected two-point function defines a positive quadratic form.

Next, we remind the readers of the so-called Källen–Lehmann representation of connected two-point functions (see, e.g., [Jost \(1965\)](#) and references given there), which says that

$$\begin{aligned} \langle \varphi^i(y) \cdot \varphi^i(0) \rangle_{R,h}^c &= \int_0^\infty d\mu^{(i)}(a^2) [-\Delta + a^2]^{-1}(y) \\ &\stackrel{d=3}{=} \int_0^\infty d\mu^{(i)}(a^2) \frac{e^{-a|y|}}{4\pi|y|}, \quad \text{for } i = 1, \dots, N, \end{aligned} \quad (15)$$

where $d\mu^{(i)} = d\mu^{(j)}$, for $i, j = 2, \dots, N$. In $d = 3$ dimensions, $\lambda|\phi|^4$ -theory is a canonical field theory (there is no field strength renormalization!). The real-time quantum fields satisfy equal-time canonical commutation relations; that is,

$$[\varphi^j(\vec{x}, t), \pi^k(\vec{y}, t)] = i\delta^{jk}\delta(\vec{x} - \vec{y}), \quad \text{where } \pi^k = \dot{\varphi}^k,$$

and these commutation relations imply that

$$\int_0^\infty d\mu^{(i)}(a^2) = 1, \quad \forall i = 1, \dots, N.$$

It then follows that

$$\langle \phi(y) \cdot \phi(0) \rangle_{R,h}^c - \frac{N}{4\pi|y|} \leq 0, \quad \forall y,$$

and, using (12) and (13), we conclude that

$$M^2 \leq \langle : |\phi(0)|^2 : \rangle_{R,h} \leq \langle \varphi^1(0) \rangle_{R,h}^2, \quad (16)$$

for $R^2 \geq R_M^2$, uniformly in $h \geq 0$. Thus, for R^2 large enough, the theory predicts “spontaneous magnetization,” in the sense that

$$\lim_{h \searrow 0} \langle \varphi^1(0) \rangle_{R,h} =: M(R) > 0. \quad (17)$$

Spontaneous magnetization implies that the $O(N)$ -symmetry of the action functional of the theory at $h = 0$ —see (6)—is spontaneously broken. For one-component fields ($N = 1$), the existence of a phase transition accompanied by spontaneous breaking of the $\phi \rightarrow -\phi$ -symmetry can also be proven in two dimensions; but the proof is more involved; (it is based on the so-called Peierls argument—see Glimm et al. (1975) and references given there). For $N \geq 2$, spontaneous magnetization, as stated in (17), implies that the Fourier transform of the two-point function satisfies a lower bound

$$\langle \hat{\varphi}^i(k) \hat{\varphi}^i(-k) \rangle_{R,h=0} \geq \frac{\Re}{|k|^2}, \quad \forall i = 2, \dots, N, \quad (18)$$

for some positive constant $\Re = \mathcal{O}(M(R)^2)$, for small $M(R)$, which shows that, in two dimensions and for $N \geq 2$, $M(R)$ must vanish at $h = 0$, for arbitrary values of R^2 , and there is no spontaneous breaking of the $O(N)$ -symmetry, because $|k|^{-2}$ is not integrable at the origin ($k = 0$) in momentum space. The lower bound in (18) can be derived from the analysis in Mermin and Wagner (1966) and Mermin (1967) and can also be extracted from the material in Section “Proof of the Goldstone theorem for Euclidean field theories.” For a more detailed analysis and further references see Wreszinski (1976), and vol. 2 of Simon (1993).

Next, I draw attention to the fact that, for $N \leq 3$, if the real part, $\text{Re}h$, of the magnetic field h does not vanish then the Green functions of the theory, such as $\langle \phi(x) \cdot \phi(0) \rangle_{R,h'}$, are analytic functions of h , and the connected Green functions decay exponentially in the separation of the field insertion points; in particular $\langle \phi(x) \cdot \phi(0) \rangle_{R,h}^c$ decays exponentially in $|x|$ if $\text{Re}h \neq 0$. This implies that, for real $h \neq 0$, the physical mass of all modes described by the theory is strictly positive. For proofs see, for example, Fröhlich and Rodríguez (2012, 2017) and references given there. But, for theories with fields of $N \geq 2$ components at $h = 0$, the Green functions have slow power-law decay if the spontaneous magnetization, $M(R)$, does not vanish. In particular, the susceptibility

$$\chi(R, h) := \int_{\mathbb{R}^3} d^3x \langle \varphi^i(x) \varphi^i(0) \rangle_{R,h}, \quad \text{for } i \geq 2, \quad (19)$$

has the property that if the spontaneous magnetization $M(R) = \lim_{h \searrow 0} \langle \varphi^1(0) \rangle_{R,h}$ is strictly positive then

$$\chi(R, h) \simeq \frac{M(R)}{h}, \quad \text{as } h \searrow 0. \quad (20)$$

Hence, if R^2 is chosen such that there is spontaneous magnetization, in the sense that $M(R) > 0$, then, at $h = 0+$, the two-point Green functions $\langle \varphi^i(x) \varphi^i(0) \rangle_{R,0+}$, $i \geq 2$, have nonintegrable decay in x , which shows that there must be massless modes in the theory. It may be appropriate to sketch the proof of (20). We consider a change of variables in the (φ^1, φ^2) -plane of field space, namely

$$\begin{aligned} \varphi_\theta^1 &:= \cos\theta \varphi^1 + \sin\theta \varphi^2, \\ \varphi_\theta^2 &:= -\sin\theta \varphi^1 + \cos\theta \varphi^2. \end{aligned} \quad (21)$$

where θ is an x -independent angle. In the following, I drop reference to the parameter R (which will be kept fixed) from my notations and rewrite the action functional, $S(\phi)$, of the theory introduced in (6) as

$$S(\phi) = \tilde{S}(\phi) - h \int d^3x \varphi^1(x),$$

where the functional $\tilde{S}(\phi)$ is manifestly $O(N)$ -invariant. Then we have that

$$\begin{aligned} 0 &= \langle \varphi^2(0) \rangle_h \\ &= \frac{1}{Z(h)} \int \mathcal{D}\phi e^{-\tilde{S}(\phi) + h \int d^3x \varphi^1(x)} \varphi^2(0) \\ &= \frac{1}{Z(h)} \int \mathcal{D}\phi_\theta e^{-\tilde{S}(\phi) + h \int d^3x \varphi_\theta^1(x)} \varphi_\theta^2(0) \end{aligned} \quad (22)$$

identically in θ , where we have used that $\tilde{S}(\phi_\theta) = \tilde{S}(\phi)$, by $O(N)$ -symmetry. We note that

$$\mathcal{D}\phi_\theta = \mathcal{D}\phi,$$

because the Jacobian of the change of variables in (21) is unity. By taking the derivative in the variable θ and subsequently setting $\theta = 0$ the identity in (22) is seen to imply that

$$\begin{aligned} 0 &= \frac{d}{d\theta} \langle \varphi^2(0) \rangle_h \Big|_{\theta=0} \\ &= \frac{1}{Z(h)} \int \mathcal{D}\phi e^{-\tilde{S}(\phi) + h \int d^3x \varphi^1(x)} \left[h \int d^3x \varphi^2(x) \right] \varphi^2(0) \\ &\quad - \frac{1}{Z(h)} \int \mathcal{D}\phi e^{-\tilde{S}(\phi) + h \int d^3x \varphi^1(x)} \varphi^1(0) \\ &= h \chi(h) - \langle \varphi^1(0) \rangle_h. \end{aligned} \quad (23)$$

After re-introducing the parameter R in our notations we see that (23) and (17) imply that

$$\chi(R, h) = h^{-1} \langle \varphi^1(0) \rangle_{R, h} \geq \frac{M(R)}{h},$$

which yields (20). The arguments presented here have been worked out in [Spencer and Fröhlich \(2013–2014\)](#).

Proof of the Goldstone theorem for Euclidean field theories

The following analysis is inspired by a paper on the Goldstone theorem; see [Symanzik \(1967\)](#).

In comparison with the previous section, we consider a somewhat more general set-up and consider an RQFT of a scalar field ϕ in $d \geq 3$ dimensions with a continuous internal symmetry described by a compact Lie group G whose Lie algebra is denoted by $\mathfrak{g}$. A symmetry transformation generated by an element $X \in \mathfrak{g}$ corresponds to a conserved Noether current $j_X^\mu(x)$, $x = (\vec{x}, t) \in \mathbb{M}^d$, of the theory; (see, e.g., [Buchholz et al. \(1986\)](#) for a somewhat abstract treatment of Noether's theorem in RQFT). In the example of $\lambda|\phi|^4$ -theory with an action functional as in (6), setting $h = 0$, the symmetry group is $G = O(N)$, and, for $X \equiv X_{ij} := E_{ij} - E_{ji}$, where E_{ij} is a matrix unit with a 1 in the position ij , for $i, j = 1, \dots, N$, the corresponding conserved Noether current is given by

$$j_{X_{ij}}^\mu(x) = i(\partial^\mu \varphi^i(x))\varphi^j(x) - i(\partial^\mu \varphi^j(x))\varphi^i(x), x \in \mathbb{M}^d. \quad (24)$$

Returning to the general framework, the field ϕ of the theory is assumed to transform under a representation π of the symmetry group G , which we assume not to contain the trivial representation of G as a subrepresentation. A generator $X \in \mathfrak{g}$ therefore acts on field space in the representation $d\pi$ of $\mathfrak{g}$, that is,

$$d\pi(X) : \phi(x) \mapsto d\pi(X)\phi(x) \equiv \phi^X(x).$$

Since the currents j_X^μ are conserved, that is, satisfy the continuity equation,

$$\partial_\mu j_X^\mu(x) = 0, \quad (25)$$

the charges

$$Q_X := \int_{t=\text{const.}} d^{d-1}x j_X^0(\vec{x}, t) \quad (26)$$

are conserved, and we have that

$$[Q_X, \phi(x)] = \phi^X(x). \quad (27)$$

We now assume that the theory has a vacuum state, denoted by $|\emptyset\rangle =: \Omega_{\phi_c}$, which is **not** invariant under the action of G on the state space of the theory, i.e, breaks the symmetry G spontaneously, with

$$\langle \Omega_{\phi_c} | \phi(x) | \Omega_{\phi_c} \rangle = \phi_c \neq 0. \quad (28)$$

Let H_{ϕ_c} denote the subgroup of G that leaves ϕ_c invariant, and let $\mathfrak{h}_{\phi_c}$ denote its Lie algebra. Then

$$\phi_c^X \equiv d\pi(X)\phi_c = 0, \quad \forall X \in \mathfrak{h}_{\phi_c}.$$

Since π does not contain the trivial representation of G as a subrepresentation, $\mathfrak{h}_{\phi_c}$ is a subspace of $\mathfrak{g}$ of dimension smaller than the dimension of $\mathfrak{g}$. For a generator $Y \in \mathfrak{g}$ that belongs to the complement, $\mathfrak{h}_{\phi_c}^\perp$, of $\mathfrak{h}_{\phi_c}$, we then have that

$$\phi_c^Y := \langle \Omega_{\phi_c} | \phi^Y(x) | \Omega_{\phi_c} \rangle \neq 0. \quad (29)$$

Combining (27) with (29), we find that

$$\langle \Omega_{\phi_c} | [Q_Y, \phi(0)] | \Omega_{\phi_c} \rangle = \langle \Omega_{\phi_c} | \phi^Y(0) | \Omega_{\phi_c} \rangle = d\pi(Y)\phi_c \equiv \phi_c^Y, \quad (30)$$

for an arbitrary $Y \in \mathfrak{h}_{\phi_c}^\perp$. On the left side of (30) we re-write Q_Y using (26) and then use a standard formula involving the Hamiltonian $H \geq 0$ of the associated RQFT. This yields

$$\begin{aligned} \phi_c^Y &= \langle \Omega_{\phi_c} | [Q_Y, \phi(0)] | \Omega_{\phi_c} \rangle \\ &= \int_{t=0} d^{d-1}x \langle \Omega_{\phi_c} | \left[j_Y^0(\vec{x}, 0), \phi(0) \right] | \Omega_{\phi_c} \rangle \\ &= \lim_{\varepsilon \searrow 0} \int d^{d-1}x \langle \Omega_{\phi_c} | j_Y^0(\vec{x}, 0) e^{-\varepsilon H} \phi(0) - \phi(0) e^{-\varepsilon H} j_Y^0(\vec{x}, 0) | \Omega_{\phi_c} \rangle \\ &= \lim_{\varepsilon \searrow 0} \int d^{d-1}x \langle [j_Y^0(\vec{x}, \varepsilon) - j_Y^0(\vec{x}, -\varepsilon)] \phi(0) \rangle, \end{aligned} \quad (31)$$

where the integrand on the very right side of these equations is a Euclidean Green or Schwinger function of the 0 component of the current j_Y^μ and the field ϕ (which, in the example of $\lambda|\phi|^4$ -theory in two or three dimensions, can be expressed by a functional integral). We define distributions $W_Y^\mu(x)$, $x = (\vec{x}, t) \in \mathbb{E}^d$, by

$$\begin{aligned} W_Y^\mu(x) &:= \left\langle j_Y^\mu(\vec{x}, t) \phi(0) \right\rangle \\ &= \begin{cases} \left\langle \Omega_{\phi_c} \left| j_Y^\mu(\vec{x}, 0) e^{-tH} \phi(0) \right| \Omega_{\phi_c} \right\rangle, & \text{for } t > 0, \\ \left\langle \Omega_{\phi_c} \left| \phi(0) e^{tH} j_Y^\mu(\vec{x}, 0) \right| \Omega_{\phi_c} \right\rangle, & \text{for } t < 0, \end{cases} \end{aligned} \quad (32)$$

where we have used that $e^{\pm tH}|\Omega_{\phi_c}\rangle = |\Omega_{\phi_c}\rangle$, for arbitrary t . Combining (30) through (32), we find that

$$\phi_c^Y = \lim_{\varepsilon \searrow 0} \int_{S_\varepsilon} d\sigma_\mu(x) W_Y^\mu(x) \neq 0, \quad (33)$$

where S_ε is the union of two oriented planes given by

$$S_\varepsilon := \bigcup_{t=\pm\varepsilon} \left\{ x \in \mathbb{R}^d \mid x = (\vec{x}, t), t = \text{const.} \right\},$$

and $d\sigma_\mu(\cdot)$ is the oriented surface measure on S_ε . Next, we use that j_Y^μ is a conserved current, that is, that it satisfies the continuity equation (25) (with X replaced by Y), which implies that

$$\partial_\mu W_Y^\mu(x) = 0, \quad \text{for } x \neq 0. \quad (34)$$

This identity will permit us to apply Gauss' theorem in a useful way. We define two "half-balls," $B_{r,\varepsilon}^+$ and $B_{r,\varepsilon}^-$, in $\mathbb{R}^d$ with oriented boundaries by

$$\begin{aligned} B_{r,\varepsilon}^+ &:= \left\{ x = (\vec{x}, t) \mid |x| \leq r, t \geq \varepsilon > 0 \right\}, \quad \text{with } |x| := \sqrt{\vec{x}^2}, \\ B_{r,\varepsilon}^- &:= \left\{ x = (\vec{x}, t) \mid |x| \leq r, t \leq -\varepsilon < 0 \right\}. \end{aligned} \quad (35)$$

Since $0 \notin B_{r,\varepsilon}^+ \cup B_{r,\varepsilon}^-$, we can apply Gauss' theorem to $W_Y^\mu|_{B_{r,\varepsilon}^+ \cup B_{r,\varepsilon}^-}$, which then yields

$$\begin{aligned} 0 \neq \phi_c^Y &= \lim_{\varepsilon \searrow 0} \left\{ \int_{S_\varepsilon} d\sigma_\mu(x) W_Y^\mu(x) + \sum_{\kappa=\pm} \underbrace{\int_{\partial B_{r,\varepsilon}^\kappa} d\sigma_\mu(x) W_Y^\mu(x)}_{=0, \text{ by (34) and Gauss' theorem}} \right\} \\ &= \int_{\partial B_r} d\sigma_\mu(x) W_Y^\mu(x), \end{aligned} \quad (36)$$

for an arbitrary $r > 0$, where B_r is a ball in $\mathbb{R}^d$ of radius r centered at the origin, $x = 0$; (the reader is invited to make a drawing to verify this). The second (last) equality in (36) follows by using Gauss' theorem again. Euclidean covariance of W_Y^μ implies that

$$W_Y^\mu(x) = \phi_c^Y \cdot x^\mu f(|x|),$$

for some rotation-invariant function f . It then follows from (36) that

$$W_Y^\mu(x) = \frac{\phi_c^Y}{s_{d-1}} \cdot \frac{x^\mu}{|x|^d}, \quad (37)$$

where s_{d-1} is the area of the $(d-1)$ -dimensional unit sphere in d dimensions. The definition of W_Y^μ in (32) and Eq. (37) show that the field ϕ and the charge density j_Y^0 couple the vacuum state, Ω_{ϕ_c} , of the theory to a massless scalar one-particle state, which describes a Goldstone boson. Apparently, there are at least as many distinct Goldstone bosons in this theory as there are linearly independent generators in the complement, $\mathfrak{h}_{\phi_c}^\perp$, of $\mathfrak{h}_{\phi_c} \subset \mathfrak{g}$. Furthermore, if $\phi_c \neq 0$ then the connected two-point function of the field ϕ has the form

$$\langle \phi(x) \cdot \phi(0) \rangle^c = \int_0^\infty d\mu(a^2) [-\Delta + a^2]^{-1}(x), \quad (38)$$

with

$$d\mu(a^2) = \Re \cdot \delta(a^2) da^2 + \text{regular at } a^2 = 0, \quad (39)$$

where $\Re$ is the residue of a one-particle pole of zero mass.

Well, we have apparently just recovered a (somewhat novel) proof of the Goldstone theorem in the imaginary-time (Euclidean) formalism of quantum field theory; (see [Symanzik \(1967\)](#) for the original arguments).

In two dimensions, the residue $\Re$ must vanish if the two-point function of the field ϕ is well defined. We thus conclude that ϕ_c must vanish, that is, continuous symmetries cannot be broken in two dimensions. This is the content of the Mermin–Wagner–Hohenberg–Coleman theorem; see [Hohenberg \(1967\)](#), [Mermin and Wagner \(1966\)](#), [Mermin \(1967\)](#), and [Coleman \(1973\)](#).

Interesting general results on spontaneous symmetry breaking, Goldstone bosons, and effective Lagrangians (also for nonrelativistic systems of condensed matter) can be found in [Leutwyler \(1994, 1997\)](#).

The example of $\lambda|\phi|^4$ -theory

We conclude this section with some remarks on the $\lambda|\phi|^4$ -theories with fields ϕ of $N = 1, 2$ or 3 real components. For $N = 1$, the symmetry group is discrete, namely $\mathbb{Z}_2$. The breaking of discrete groups does not give rise to Goldstone bosons and is possible not only in three but also in two dimensions, as shown in [Glimm et al. \(1975\)](#), where a Peierls-type argument is used to prove the existence of a phase transition accompanied by the breaking of the $\mathbb{Z}_2$ -symmetry. For $N = 2$, the symmetry group is $U(1)$, and symmetry breaking is only possible in dimension $d \geq 3$. However, one expects that, in two dimensions, the theory exhibits a Berezinskii–Kosterlitz–Thouless transition ([Kosterlitz and Thouless, 1973](#)) from a massive to a massless phase, but without spontaneous symmetry breaking. The existence of this transition has been proven rigorously for the classical XY-model on the square lattice and the related Villain model, as well as for some other lattice models, such as the two-component Coulomb gas, in [Fröhlich and Spencer \(1981\)](#); see also [Falco \(2012\)](#). But it remains conjectural for the continuum $\lambda|\phi|^4$ -theory of a complex scalar field. For $N \geq 3$, many people expect that, in two dimensions, the theory is always massive, that is, the lowest mass in the theory is strictly positive; see, for example, [Polyakov \(1975\)](#).

We now turn to the $\lambda|\phi|^4$ -theories with $N \geq 2$ components in three dimensions. For these theories, we have established the existence of a phase transition to a phase with a nonvanishing vacuum expectation value of the field ϕ in a vanishing magnetic field $h = 0 +$ signaling spontaneous symmetry breaking. The analysis presented above shows that if the $O(N)$ -symmetry is broken, then there are $N - 1$ distinct Goldstone bosons.

The Lee–Yang theorem implies that, for $N \leq 3$, the connected Green functions of the theory are analytic in h and have exponential decay in the separation of their arguments, provided $\text{Re} h \neq 0$. As a corollary, it follows that, for real $h \neq 0$, the theory has a strictly positive mass gap $m(h)$, that is, the masses of all excitations in the theory are bounded below by $m(h) > 0$.

The results in Section “The phase transition in the $\lambda|\phi|^4$ -Euclidean field theory in three dimensions” yield information on some of the critical exponents of the theories with $N = 2, 3$. We return to Eq. (20), which says that the susceptibility $\chi(h)$ of the theory diverges like $\frac{1}{h^\nu}$ as $h \rightarrow 0$, provided the “spontaneous magnetization” $M(R)$ (see (17)) does not vanish. A related bound on the mass gap $m(h)$ is plausible, but remains conjectural. I briefly sketch it here. We have seen in (38) and (39) that if there is spontaneous symmetry breaking, then the connected two-point Green function has a one-particle pole at zero mass, which, for the example of $\lambda|\phi|^4$ -theory, with $N \geq 2$ and at $h = 0 +$, implies that

$$\langle \varphi^i(x) \cdot \varphi^i(0) \rangle_{h=0+} = \Re [-\Delta]^{-1}(x) + \int_0^\infty d\mu_{\text{reg}}(a^2) [-\Delta + a^2]^{-1}(x), \quad \text{for } i \geq 2, \quad (40)$$

where the residue $\Re$ of the one-particle pole at zero mass is strictly positive in the symmetry-broken phase, and the measure $d\mu_{\text{reg}}(a^2)$ is regular at $a^2 = 0$. (It is assumed here that the parameter R^2 is large enough such that there is spontaneous symmetry breaking; but we do not display the R -dependence explicitly.) If $h > 0$, this representation takes the form

$$\langle \varphi^i(x) \cdot \varphi^i(0) \rangle_h = \Re(h) [-\Delta + m^2(h)]^{-1}(x) + \int_{m^2(h)}^\infty d\tilde{\mu}(a^2) [-\Delta + a^2]^{-1}(x), \quad i \geq 2, \quad (41)$$

where the physical mass, that is, the inverse correlation length, $m(h)$, is strictly positive, as follows from the Lee–Yang theorem, and $d\tilde{\mu}(a^2)$ is regular at $a^2 = m^2(h)$. It is plausible to expect that $\Re(h) \approx \Re$ is strictly positive, for $h > 0$ small enough, that is,

$$\Re(h) \geq \Re_* > 0, \quad \text{for } h > 0 \text{ small enough.} \quad (42)$$

Using convergent expansions, this expectation is known to be true if h is real and $|h|$ is large enough. However, the strict positivity of $\Re(h)$ for small, but positive values of h is a conjecture that has not been proven so far. Assuming that it holds true, we conclude from (41) and (42) that, for $i \geq 2$,

$$\chi(h) = \int d^3x \langle \varphi^i(x) \cdot \varphi^i(0) \rangle_h \geq \frac{\Re_*}{m^2(h)}, \quad \text{with } \Re_* > 0. \quad (43)$$

Combining this lower bound with expression (20) for the susceptibility $\chi(h)$, we find that the mass gap $m(h)$ of the theory satisfies the lower bound (predicted by heuristic arguments)

$$m(h) \geq \text{const.} \sqrt{h}, \quad \text{as } h \searrow 0. \quad (44)$$

We remark that it follows from the Lee–Yang theorem that $m(h)$ is bounded below by $\text{const.} h$, for small values of $h > 0$. One can rigorously prove a related upper bound on $m(h)$ as follows: From the Källen–Lehmann representation,

$$\langle \varphi^i(y) \cdot \varphi^i(0) \rangle_{\rho, h}^c = \int_{m^2(h)}^{\infty} d\mu^{(i)}(a^2) [-\Delta + a^2]^{-1}(y), \quad i \geq 2,$$

see (15), the fact that $\int d\mu^{(i)}(a^2) = 1$, and (20) we derive that

$$\frac{M(R)}{h} \leq \chi(h) \leq \frac{1}{m(h)^2}$$

hence if there is spontaneous magnetization ($M(R) > 0$) then, for positive h ,

$$m(h) \leq \text{const.} \sqrt{h}, \quad \text{as } h \searrow 0. \quad (45)$$

It is evident that whatever is written here for $h > 0$ also holds for $h < 0$ (by replacing φ^1 by $-\varphi^1$).

Eqs. (20), (44), and (45) are results on critical exponents describing the behavior of the susceptibility and of the mass gap, as $h \searrow 0$, assuming that the spontaneous magnetization is strictly positive. It would be of considerable interest to understand the behavior of the spontaneous magnetization, $M(R)$, defined in (17), as the parameter R^2 approaches the phase-transition point, that is, $R^2 \searrow R_c^2$, with $M(R) = 0$, for $R^2 < R_c^2$. One expects that $M(R) \searrow 0$ continuously, as $R^2 \searrow R_c^2$. But this has only been proven rigorously for the three-dimensional Ising model (corresponding to $N = 1$), with $M(R) \geq \mathcal{O}([R^2 - R_c^2]^{1/2})$; see Aizenman et al. (2015).

One may ask how, in zero magnetic field, $h = 0$, the susceptibility, $\chi(R, h = 0)$, and the mass gap, $m(R, h = 0)$, behave when $R^2 \nearrow R_c^2$. A correlation inequality for the connected four-point (Ursell) function due to Lebowitz (1974) implies that, for one-component real fields ($N = 1$), $\chi(R, 0)$ diverges at least as rapidly as $(R_c^2 - R^2)^{-1}$, and the mass gap $m(R, 0)$ tends to 0 continuously, as $R^2 \nearrow R_c^2$; see Glimm and Jaffe (1974) and McBryan and Rosen (1976). These results are also known to hold for complex scalar fields ($N = 2$), but not for $N \geq 3$.

The reader may wonder why the $\lambda|\phi|^4$ -theory in four (or more) dimensions has not been considered so far. The reason is that if all ultraviolet cutoffs are removed this theory is expected to be equivalent to a (generalized) free field. Assuming that one regularizes the theory by putting it on a hypercubic lattice, this result has been proven for the theories in dimension $d > 4$, with fields of $N = 1$ or 2 components, in Aizenman (1982) and Fröhlich (1982). In four dimensions, this result is only known for the scaling limit of the Ising model and for $\lambda\phi_4^4$ -theory of a one-component real scalar field, the very beautiful, subtle proof appearing in Aizenman and Duminil-Copin (2021). Partial results for $\lambda|\phi|^4$ -theory of a complex scalar field in four dimensions have been reported in Fröhlich (1982); but these results remain incomplete. For $N \geq 3$, there are no rigorous results known, yet (except at weak coupling).

These remarks motivate us to consider classical and quantum lattice systems, which do not have an ultraviolet (short-distance) problem. I will provide a guide to the literature in the next section, but won't discuss any details.

Phase transitions and symmetry breaking in classical and quantum lattice systems

For applications in statistical mechanics and condensed matter physics, classical and quantum lattice systems are usually more relevant than continuum field theories, although the latter tend to describe critical phenomena of lattice systems near continuous phase transitions.

We limit our review to sketching some results for classical or quantum spin systems on a lattice $\mathbb{Z}^d$, with $d = 2, 3, 4$. The Hamiltonian of such systems is given by

$$H \equiv H(\{\vec{S}\}) := - \sum_{x, y \in \mathbb{Z}^d} \left\{ J_{\perp}(x - y) \left[S_x^1 S_y^1 + S_x^2 S_y^2 \right] + J_{\parallel}(x - y) S_x^3 S_y^3 \right\} - h \sum_{x \in \mathbb{Z}^d} S_x^3, \quad (46)$$

where $J_{\perp}(x - y)$ and $J_{\parallel}(x - y)$ are exchange couplings (see Heisenberg, 1928), h is proportional to the strength of an external magnetic field in the 3-direction, and $\vec{S}_x = (S_x^1, S_x^2, S_x^3)$ is either a classical spin in $\mathbb{R}^3$ or a quantum spin with spin quantum number $s = \frac{1}{2}, 1, \dots$

- (i) If $J_{\parallel}(x - y) \gg |J_{\perp}(x - y)|$, $\forall x, y$, this Hamiltonian describes uniaxial magnetism. For classical spins or quantum spins with $s = \frac{1}{2}$, the model behaves like an Ising model with $J_{\perp} \equiv 0$. Phase transitions only occur when $h = 0$, in which case the model has a $\mathbb{Z}_2$ -symmetry. Rigorous results for quantum spins can be found in Ginibre (1969) and Kennedy (1985) and references given there.
- (ii) If $J_{\perp}(x - y) \gg |J_{\parallel}(x - y)|$, $\forall x, y$, the model describes a classical or quantum XY (rotator) model, which has a continuous symmetry $U(1)$.
- (iii) If $J_{\perp} \equiv J_{\parallel} = J$ the model describes an isotropic magnet and, for $h = 0$, has a continuous symmetry given by $SO(3)$ or $\widetilde{SO}(3) = SU(2)$.

Let us first consider the classical models. They have been studied in Fröhlich et al. (1976) and, using totally different methods, in Garban and Spencer (2022); and references given there. We briefly review the results and methods used in Fröhlich et al. (1976), which are inspired by properties of RQFT's and EFT's, in particular by the Källen–Lehmann representation (15).

For classical spin systems, the number of components of the spin $\vec{S}$ is irrelevant; we may replace (S^1, S^2) by $(S^1, \dots, S^{N-1})$ and S^3 by S^N , $N = 1, 2, 3, \dots$. We begin by explaining what it means for exchange couplings J to be "reflection positive." Let Π be a

hyperplane in $\mathbb{R}^d$ of codimension 1 that lies in between two lattice planes of $\mathbb{Z}^d$ (viewed as a subset of $\mathbb{R}^d$), and let θ denote reflection at Π . Then the two sites $x \in \mathbb{Z}^d$ and $\theta x \in \mathbb{Z}^d$ lie symmetrically on two different sides of the hyperplane Π . We define $\mathbb{Z}_+^d$ and $\mathbb{Z}_-^d$ to be the two half-lattices on the two different sides of the hyperplane Π . Let $J(x-y), x, y \in \mathbb{Z}^d$, be exchange couplings.

Definition: J is said to be “reflection positive” iff

$$\sum_{x, y \in \mathbb{Z}_+^d} J(x - \theta y) z_x \bar{z}_y \geq 0, \quad (47)$$

for an arbitrary complex-valued function z on the half-lattice $\mathbb{Z}_+^d$.

The equilibrium state of a classical spin system with a Hamiltonian given by (46) at inverse temperature β is given by the formal probability measure

$$dP(\{\vec{S}\}) := \frac{1}{Z_\beta} e^{-\beta H(\{\vec{S}\})} \prod_{x \in \mathbb{Z}^d} d\rho(\vec{S}_x). \quad (48)$$

where $d\rho(\vec{S})$ is a finite measure on $\mathbb{R}^N$, for example

$$d\rho(\vec{S}) = \begin{cases} \exp\left(-\frac{\lambda}{4!} \left[|\vec{S}|^2 - R^2\right]^2\right) d\vec{S}, & \text{or} \\ \delta(|\vec{S}|^2 - R^2) d\vec{S}, \end{cases} \quad (49)$$

with $d\vec{S}$ the Lebesgue measure on $\mathbb{R}^N, N = 1, 2, 3, \dots$, and Z_β is the partition function, which is chosen such that $\int dP(\{\vec{S}\}) = 1$. Since we have not normalized the exchange couplings, we may henceforth set $\beta = 1$ and omit it. Expectations of products of components of spins with respect to the measure $dP(\{\vec{S}\})$ are denoted by $\langle(\cdot)\rangle_{J_\perp, J_\parallel, h} \equiv \langle(\cdot)\rangle$.

It turns out that, for classical spin systems with a Hamiltonian given by (46) and reflection-positive exchange couplings $J_\perp$ and $J_\parallel$ satisfying (47), there is an analog of the Källen–Lehmann representation in the form of upper bounds, so-called **Infrared Bounds**, on the Fourier transforms of connected spin–spin correlation functions: for $k \neq 0$,

$$\begin{aligned} 0 < \langle \hat{S}^i(k) \hat{S}^i(-k) \rangle &\leq \frac{1}{\hat{J}_\perp(0) - \hat{J}_\perp(k)}, \quad \text{for } i = 1, \dots, N-1, \\ 0 < \langle \hat{S}^N(k) \hat{S}^N(-k) \rangle &\leq \frac{1}{\hat{J}_\parallel(0) - \hat{J}_\parallel(k)}, \end{aligned} \quad (50)$$

where $\widehat{(\cdot)}$ denotes Fourier transformation, that is $\hat{S}^i(k)$ is the Fourier transform of S_x^i , for $i = 1, \dots, N$, and $k \in B$, where B is the Brillouin zone (i.e., a d -dimensional torus, for the lattice $\mathbb{Z}^d$). At the origin, $k = 0$, in quasi-momentum space, these two-point functions may include δ -function contributions, $M_i^2 \delta_0(k) d^d k$, where the constants M_i^2 manifest long-range order (LRO), for $i = 1, 2, \dots, N$. In an extremal equilibrium state, the absolute value of the spontaneous magnetization is then given (in average) by $\mathcal{M} = \sqrt{\sum_{i=1}^N M_i^2}$. The bounds in (50) have been established rigorously in Fröhlich et al. (1976) and Fröhlich et al. (1978).

We now show that, in $d \geq 3$ dimensions and for exchange couplings $J_\perp$ and $J_\parallel$ of short range, the quantity $\mathcal{M}$ must be strictly positive, provided the parameter R is large enough. First we note that, for $d\rho$ as in (49),

$$\sum_{i=1}^N \int_B d^d k \langle \hat{S}^i(k) \hat{S}^i(-k) \rangle = \langle \vec{S}_0 \cdot \vec{S}_0 \rangle = c \cdot R^2, \quad (51)$$

for some strictly positive constant c . (This is obvious for the choice $d\rho(\vec{S}) = \delta(|\vec{S}|^2 - R^2) d\vec{S}$, in which case $c = 1$.) But, by (50), the left side is bounded from above by

$$\langle \vec{S}_0 \cdot \vec{S}_0 \rangle \leq \int_B d^d k \left[\frac{N-1}{\hat{J}_\perp(0) - \hat{J}_\perp(k)} + \frac{1}{\hat{J}_\parallel(0) - \hat{J}_\parallel(k)} \right] + \mathcal{M}^2. \quad (52)$$

If the exchange couplings $J_\perp$ and $J_\parallel$ are of short range, then

$$[\hat{J}_\alpha(0) - \hat{J}_\alpha(k)]^{-1} \leq J_\alpha^{-1} |k|^{-2}, \quad (53)$$

for some positive constants J_α , with $\alpha = \perp$ or $\parallel$. Taking $J := \min(J_\perp, J_\parallel)$ we find that

$$c \cdot R^2 = \langle \vec{S}_0 \cdot \vec{S}_0 \rangle \leq \frac{N}{J} I_d + \mathcal{M}^2. \quad (54)$$

where $I_d = \int_B d^d k \frac{1}{k^2}$. Obviously, I_d diverges in $d = 1$ and 2 dimensions, in which case (54) is useless. But I_d is finite for $d \geq 3$, and it then follows that

$$\mathcal{M}^2 \geq c \cdot R^2 - \frac{N}{J} I_d > 0, \quad \text{for } R^2 \text{ big enough,}$$

that is, there is spontaneous magnetization and symmetry breaking if R^2 or J are big enough.

For the Ising model ($N = 1$) and the classical XY model ($N = 2$), these results on the existence of phase transitions accompanied by symmetry breaking can be extended to a large class of not necessarily translation-invariant and not necessarily reflection-positive exchange couplings by using what one calls “correlation inequalities.” The relevant inequalities can be found in [Messenger et al. \(1978\)](#).

One expects that if $J_{\parallel} > J_{\perp}$, then the spontaneous magnetization is parallel to the N -axis (with $N = 3$ for the Hamiltonian in (46)). In this case, the discrete symmetry $S^N \rightarrow -S^N$ is broken; for results in this direction, see [Kennedy \(1985\)](#) and references given there. But if $J_{\perp} > J_{\parallel}$, then the spontaneous magnetization is expected to lie in the plane $\{\vec{S} \mid S^N = 0\}$, and the continuous symmetry $O(N - 1)$ of the Hamiltonian is broken, which, for $N \geq 3$, is accompanied by the emergence of $N - 2$ Goldstone bosons. If $J_{\parallel} = J_{\perp} \equiv J$, then the model exhibits an $O(N)$ -symmetry, and the spontaneous magnetization can have an arbitrary direction in $\mathbb{R}^N$, which can be chosen by introducing a small symmetry breaking term, $-\hbar \cdot \sum_x \vec{S}_x$, in the Hamiltonian and letting $|\hbar|$ tend to 0 eventually. All these predictions can be shown to hold rigorously for $N = 1, 2, 3$, under suitable assumptions on the parameters.

It may be appropriate to sketch a heuristic idea that originally inspired a stronger (exponential) version of the Infrared Bounds in (50), and which could then be extended to quantum lattice systems. We consider a canonical quantum field theory of a real scalar field φ on d space-time dimensions with a Hamiltonian, denoted by H , whose energy spectrum is bounded from below by 0. Such a theory (if it existed) would have the following properties:

$$\begin{aligned} \dot{\varphi}(\vec{x}, t) &= i [H, \varphi(\vec{x}, t)] =: \pi(\vec{x}, t), \quad \text{with} \\ [\varphi(\vec{x}, t), \pi(\vec{y}, t)] &= i \delta(\vec{x} - \vec{y}), \end{aligned} \quad (55)$$

where t denotes time and $\vec{x}$ is a point in space. Let f and g be real-valued test functions on $\mathbb{R}^{d-1}$, and let

$$\varphi(f, t) := \int_{\mathbb{R}^{d-1}} d\vec{x} \, \varphi(\vec{x}, t) f(\vec{x}), \quad (56)$$

$$\pi(g, t) := \int_{\mathbb{R}^{d-1}} d\vec{x} \, \pi(\vec{x}, t) g(\vec{x}), \quad \text{with} \quad (57)$$

$$[\varphi(f, t), \pi(g, t)] = i \int_{\mathbb{R}^{d-1}} d\vec{x} \, f(\vec{x}) g(\vec{x}) \equiv i \langle f, g \rangle. \quad (58)$$

Since φ is a real field, we may expect that, at all times t , $\varphi(f, t)$ is a self-adjoint operator on the Hilbert space, $\mathcal{H}$, of the theory. From our assumption that $H \geq 0$ it follows that $U H U^* \geq 0$, for an arbitrary unitary operator U on $\mathcal{H}$, and we then find that

$$0 \leq e^{i\varphi(f, t)} H e^{-i\varphi(f, t)} = H - \pi(f, t) + \frac{1}{2} \|f\|_2^2 \mathbf{1}, \quad (59)$$

where $\|f\|_2^2 := \langle f, f \rangle$. Using a Feynman–Kac formula, one can translate this bound to one that holds for a corresponding EFT at imaginary time. We denote the Euclidean field corresponding to the quantum field φ by ϕ , as before, and expectations with respect to the functional measure describing the EFT corresponding to the QFT are denoted by $\langle \cdot \rangle$. For a real-valued test function h on $\mathbb{R}^d$, we define $\phi(h) := \int d^d x \, \phi(x) h(x)$. Then (59) implies that

$$\left\langle e^{\frac{\partial \phi(h)}{\partial t}} \right\rangle \leq e^{\frac{1}{2} \|h\|_2^2}.$$

By Euclidean invariance, it then follows that

$$\langle \exp[\nabla \phi(\underline{h})] \rangle \leq e^{\frac{1}{2} \|\underline{h}\|_2^2}, \quad (60)$$

where $\underline{h} = (h_1, \dots, h_d)$ is a d -tuple of test functions. This bound readily implies that, in momentum space and for $k \neq 0$,

$$\langle \hat{\phi}(k) \hat{\phi}(-k) \rangle \leq \frac{1}{|k|^2},$$

which is an Infrared Bound similar to (50) in the special case where $N = 1$ and where $J_{\parallel}$ is a nearest-neighbor coupling of strength 1. Obviously, one can extend these arguments to canonical theories of N -component real fields, $\vec{\varphi} = (\varphi^1, \dots, \varphi^N)$, $N \geq 2$. (Of course, the bound on $\langle \hat{\phi}(k) \hat{\phi}(-k) \rangle$ also follows from the Källén–Lehmann representation (15).)

For classical lattice spin systems with nearest-neighbor exchange couplings, bounds of the form of (60) have first been proven in [Fröhlich et al. \(1976\)](#). They were subsequently extended, mutatis mutandis, to classical models with general reflection-positive exchange coupling, including long-range couplings, in [Fröhlich et al. \(1978\)](#) and to quantum spin systems in [Dyson et al. \(1978\)](#).

A much more ambitious, more robust analysis of classical lattice spin systems with phase transitions accompanied by the spontaneous breaking of continuous $O(N)$ -symmetries has been undertaken in [Balaban \(1998\)](#) and [Balaban and O’Carroll \(1999\)](#), using mathematically controlled renormalization group methods. (See also [Bauerschmidt et al. \(2021\)](#) for a somewhat related, but simpler analysis of a different model.)

A new, quite surprising and original approach to proving the existence of phase transitions accompanied by spontaneous symmetry breaking has been proposed in [Garban and Spencer \(2022\)](#). The advantage of their method is that it also applies to

classical models that are neither translation-invariant nor do they satisfy Reflection Positivity. The price to pay is that the models describe disordered systems and have random exchange couplings. (For the Ising- and the classical XY model, one can, however, use the correlation inequalities in [Messager et al. \(1978\)](#) to extend their results to the usual choice of exchange couplings; see [Garban and Spencer, 2022](#).)

It turns out that Infrared Bounds analogous to those in (50)—but for so-called Duhamel two-point correlations—can also be proven for quantum lattice spin systems satisfying Reflection Positivity, as discovered in [Dyson et al. \(1978\)](#). It turns out that, among the quantum Heisenberg models, only the antiferromagnets satisfy Reflection Positivity, but not the ferromagnets. For antiferromagnets, the Infrared Bounds can be used to establish phase transitions accompanied by spontaneous symmetry breaking and the emergence of Goldstone modes (magnons); see [Dyson et al. \(1978\)](#). More general results on phase transitions and spontaneous symmetry breaking for a large family of quantum lattice systems satisfying Reflection Positivity have been established in [Fröhlich et al. \(1978\)](#) and [Albert et al. \(2006\)](#); see also [Fröhlich \(1978, 2011\)](#) for reviews. I cannot go into any details about these results. For the isotropic quantum Heisenberg ferromagnet on the complete graph, the existence of a phase transition accompanied by the spontaneous breaking of the $SU(2)$ -symmetry has been proven in [Björnberg et al. \(2020\)](#), using exact calculations that do not rely on Reflection Positivity; but rigorous results concerning phase transitions in isotropic quantum Heisenberg ferromagnets with continuous internal symmetries on finite-dimensional lattices are not known so far.

I conclude this review with a few comments on the Ising model and the classical XY model. By Kramers–Wannier duality, these models are equivalent to gases of “topological defects.” For the Ising model, these defects are domain walls (also called Peierls contours) separating domains with opposite spin orientation. For the XY model the defects are (codimension-2) vortices. It turns out that, in dimension $d \geq 2$ and at low temperatures, these defect gases are dilute. This feature enables one to analyze them by using mathematically controlled versions of energy-entropy arguments underpinned by “multiscale analysis.” For the Ising model, this strategy is implemented in what is commonly called a “Peierls argument,” in honor of its inventor. For the XY model, the analysis is considerably more subtle, due to the presence of massless Goldstone modes at low temperatures. In particular, the analysis of the low-temperature phase of the two-dimensional classical XY model, viewed as a dilute gas of point vortices with long-range (Coulomb) interactions, is really rather involved. An interesting, fairly precise upper bound on spin–spin correlations in the two-dimensional XY model at low temperatures has been proven in [McBryan and Spencer \(1977\)](#). Techniques (involving complex translations in the space of spin configurations) developed in this paper have provided some of the tools used in [Fröhlich and Spencer \(1981\)](#), where, using rather heavy multiscale analysis, the existence of the Kosterlitz–Thouless transition for the two-dimensional classical XY model and other related models has been established rigorously; see also [Falco \(2012\)](#). New, simpler proofs have recently appeared in [Lammers \(2022, 2023\)](#) (and references given there).

One of the key results established in [McBryan and Spencer \(1977\)](#) and [Fröhlich and Spencer \(1981\)](#) is the following bound on the spin–spin correlation. For ferromagnetic exchange couplings $J > J_c$, where J_c is the coupling at which the Kosterlitz–Thouless transition occurs,

$$\begin{aligned} \langle \vec{S}_0 \cdot \vec{S}_x \rangle_{J,h=0} &\simeq \mathcal{O}\left(|x|^{-\{1/2\pi\varepsilon(J)\}}\right), \quad \text{with} \\ 0 < \varepsilon(J) &\rightarrow J, \quad \text{as } J \rightarrow \infty. \end{aligned} \quad (61)$$

Here, $\vec{S}_x = (\cos \theta_x, \sin \theta_x)$, $\theta_x \in [0, 2\pi)$, is the planar spin variable of the classical XY model at site $x \in \mathbb{Z}^2$, and the external magnetic field h vanishes, $h = 0$. The Lee–Yang theorem, which holds for the classical XY model, implies that the susceptibility

$$\chi(J, h) = \sum_{x \in \mathbb{Z}^2} \langle \vec{S}_0 \cdot \vec{S}_x \rangle_{J,h}$$

is finite if $h > 0$. By (61), $\chi(J, h)$ diverges, as $h \searrow 0$, provided J is large enough. The magnetization, $M(J, h)$, is nonzero, for $h > 0$, but approaches 0, as $h \searrow 0$, by the Mermin–Wagner–Hohenberg theorem ([Hohenberg, 1967](#); [Mermin and Wagner, 1966](#); [Mermin, 1967](#)). Using that

$$\chi(J, h) = \frac{M(J, h)}{h},$$

see (20), we conclude that, for J large enough,

$$\begin{aligned} M(J, h) &\rightarrow 0, \quad \text{but } \frac{M(J, h)}{h} \text{ diverges, as } h \searrow 0, \quad \text{and} \\ \chi(J, h) &= o(h^{-1}), \quad \text{as } h \searrow 0, \end{aligned} \quad (62)$$

while, for $J < J_c$ where the spin–spin correlation decays exponentially, as $|x| \rightarrow \infty$, and the susceptibility remains finite, as $h \searrow 0$, we have that $M(J, h) \propto h$, as $h \searrow 0$.

For the three-dimensional classical XY model, the analysis is simpler, because, in $d = 3$, the vortices are one-dimensional objects and form loops. At high temperatures, these vortex loops condense; but, at low temperatures, they form a dilute gas. They have long-range interactions mediated by massless Goldstone modes. Somewhat surprisingly, these long-range interactions do not cause any major complications in the mathematical analysis of the low-temperature phase of the model. In fact, the vortex-loop

representation has been used to rigorously prove that, at low enough temperatures, the three-dimensional classical XY model has spontaneous magnetization and that its connected spin–spin correlations decay very slowly, namely like r^{-1} , where r is the distance between the spin insertion points. It is easy to show that, at high temperatures, the spin–spin correlations decay exponentially fast. These findings establish again the existence of a phase transition accompanied by the spontaneous breaking of a $U(1)$ -symmetry and the emergence of Goldstone bosons; see Fröhlich and Spencer (1983). Translation invariance of the Hamiltonian is not essential in this method.

Ideas somewhat related to those in Fröhlich and Spencer (1983) have earlier been used in Guth (1980) in an analysis of the deconfining transition in the four-dimensional $U(1)$ -lattice gauge theory; see also Fröhlich and Spencer (1982).

Conclusion

I hope this short review convinces the reader that many nontrivial facts about phase transitions accompanied by spontaneous symmetry breaking and about Goldstone bosons of considerable interest in condensed matter and particle physics are now known in the form of mathematically precise results. Work on this subject has given rise to many important insights into properties of physical systems and to the development of numerous interesting techniques of analysis that can also be used in other contexts. Ideas from statistical and condensed matter physics have been fruitfully imported into particle physics and quantum field theory, and conversely. Without this cross-fertilization, many significant results would presumably not have been found, yet.

I expect that I have quoted sufficiently much of the relevant literature to enable the reader to access without effort the nitty-gritty of the topics discussed in this review. (I offer my apologies to all colleagues whose work I should have quoted, but did not.)

Despite all the progress that has been made during more than half a century, many important questions remain open, at least if one insists on adhering to the standards of mathematical physics. Among the most important such questions are the following ones.

1. Find a continuum model with a translation-invariant Hamiltonian for which one can prove that the ground-state and the extremal low-temperature equilibrium states break translation invariance spontaneously and exhibit crystalline ordering.
2. Show that translation-invariant interacting Bose gases with physically realistic repulsive two-body interactions can exhibit Bose–Einstein condensation as the temperature is lowered at a fixed, positive density.
3. Show that the isotropic quantum Heisenberg ferromagnet in $d \geq 3$ dimensions undergoes a phase transition accompanied by the spontaneous breaking of its $SU(2)$ -symmetry.
4. Show that the quantum-mechanical XY model and the $\lambda|\phi|^4$ -theory of a complex scalar field in two dimensions undergo a Kosterlitz–Thouless transition.
5. Prove rigorously that the classical Heisenberg model and the classical N -vector models, with $N > 3$, in two dimensions have a strictly finite correlation length at all positive temperatures.
6. Extend the results in Aizenman et al. (2015) and Aizenman and Duminil-Copin (2021) concerning the magnetization in the three-dimensional Ising model, and the Gaussian nature of the scaling limit of the four-dimensional Ising- and $\lambda\phi^4$ -model ($N = 1$), respectively, to two-component models, in particular to the classical XY model.

Acknowledgments

This review could not have been written without my collaborations, mostly many years ago, with E. H. Lieb, B. Simon, and T. Spencer. They have taught me very many important things about statistical mechanics and quantum field theory. My collaboration and my countless discussions, also in more recent times, with T. Spencer count among the highlights in my scientific life, and I am deeply grateful to him for his generosity and his friendship. I have profited from interactions and collaboration with numerous other colleagues, postdocs and PhD students, too many to list them all.

I thank T. Chakraborty for encouraging me to write this review and for his patience.

Abstract

Collective dynamics of many particle systems is tightly linked to their underlying symmetry and phase transitions. Higgs and Nambu–Goldstone (NG) modes are, respectively, collective amplitude and phase modes of the order parameter that are widely observed in various physical systems at different energy scales, ranging from magnets, superfluids, and superconductors to our universe. The Higgs mode is a massive excitation, which is a condensed-matter analog of Higgs particle in high-energy physics, while the NG mode is a massless excitation that appears when a continuous symmetry is spontaneously broken. They provide important information on the fundamental aspects of many particle systems, such as symmetry, phases, dynamics, and response to external fields. In this article, we review the physics of Higgs and NG modes in condensed matter physics. Especially, we focus on the development on the study of collective modes in superconductors and cold-atom systems.

Key points

- Introduces collective modes of an order parameter in condensed matter physics, including Higgs and Nambu–Goldstone modes.
- Describes basic theories for Higgs and Nambu–Goldstone modes in superconductors and cold-atom systems (including fermionic and bosonic superfluids).
- Reviews experimental observations of Higgs and Nambu–Goldstone modes in condensed matter systems.

Introduction

A phenomenon of phase transition is widely observed in various physical systems at different energy scales, ranging from condensed-matter to high-energy physics. For example, when temperature decreases, a paramagnet turns into a ferromagnet, and a metal turns into a superconductor. Those phenomena can be universally understood with the concept of spontaneous symmetry breaking: Physical laws are invariant under a certain symmetry transformation while a physically realized state at low energy does not necessarily exhibit the same symmetry. In the case of magnets having spin rotation symmetry, individual spins are randomly oriented at high temperature, whereas at low temperature, they are aligned to one particular direction, which is spontaneously chosen. In the case of superconductors, a complex phase of a macroscopic wavefunction of electrons is aligned spontaneously.

In the conventional Landau paradigm, phase transition is characterized by an order parameter, which grows in ordered phases, such as magnetization or condensate (superfluid) density. When a continuous symmetry is spontaneously broken, there typically appear two types of collective motions of the order parameter: One is a phase fluctuation of the order parameter and the other is an amplitude fluctuation of the order parameter (Fig. 1). The former is often referred to as Nambu–Goldstone (NG) mode while the latter is called Higgs mode, which recently attracts interests in condensed matter physics. As the name suggests, the Higgs mode is a condensed-matter analog of a Higgs particle in high-energy physics, which emerges as a result of quantization of the amplitude fluctuation of a complex scalar field. The Higgs particle plays an important role in generating a mass of gauge fields due to the Higgs mechanism, making a force mediated by gauge bosons short-ranged.

Historically, on the other hand, the physics of Higgs particle and Higgs mechanism arose from the study of superconductivity. The macroscopic phenomenological theory of superconductivity had been developed by Ginzburg and Landau (1950), which can be viewed as a nonrelativistic version of the complex scalar field theory adopted by Higgs and others in the study of the Higgs mechanism. The microscopic theory of superconductivity had been presented by Bardeen et al. (1957), known as the BCS theory,

Fig. 1 Free-energy surface in the plane of a complex order parameter ψ . The red (blue) arrows represent Higgs (Nambu–Goldstone) mode, corresponding to amplitude (phase) fluctuation of the order parameter.

which had a broad impact on various branches of physics. In 1958, just one year after the BCS theory, Anderson and Bogoliubov had already discussed collective modes in superconductors (Bogoliubov et al., 1958; Anderson, 1958a, b). Especially, Anderson mentioned the existence of what is known as the Higgs mode in superconductors, whose energy was found to be twice as large as the superconducting gap. Physically, the Higgs mode in superconductors corresponds to a collective oscillation of the superfluid density (density of condensed Cooper pairs), which should be distinguished from an individual excitation of Cooper-pair breaking.

Stimulated by the development of the BCS theory, Nambu had introduced the concept of spontaneous symmetry breaking in particle physics. Based on an analogy with the BCS theory (Nambu, 1960), a possibility of spontaneous symmetry breaking is postulated for a vacuum ground state in a relativistic field theory (Nambu and Jona-Lasinio, 1961; Goldstone, 1961). It was found that a massless boson appears as a phase fluctuation of the order parameter in a symmetry broken phase, in much the same way as a spin wave appears as a collective excitation in magnets. In parallel, Goldstone and others proved a theorem (Goldstone et al., 1962) that massless particles must appear when a continuous symmetry is spontaneously broken in a relativistic field theory, and the number of those correspond to the number of degrees of broken symmetries. Later, the theorem has been extended to nonrelativistic cases (Watanabe and Murayama, 2012; Hidaka, 2013), where the counting rule of the NG modes has been established.

In the application of symmetry breaking in particle physics, one has to avoid Goldstone’s theorem since no such massless particle had been observed in our universe. In 1964, Englert, Brout, Higgs, and others had noticed that there is a way to go around Goldstone’s theorem when the system is coupled to gauge fields (Englert and Brout, 1964; Higgs, 1964; Guralnik et al., 1964): The phase mode is absorbed into the longitudinal component of gauge fields, which results in generating a mass of gauge bosons (Higgs mechanism). What remains after this is the amplitude mode of the scalar field, which corresponds to a massive scalar particle (Higgs boson). In 2012, the Higgs particle has been finally discovered in the LHC experiment at CERN (ATLAS Collaboration, 2012; CMS Collaboration, 2012), after almost 50 years since the theoretical prediction.

It should be emphasized that the Higgs mechanism had been discussed earlier by Anderson in the context of superconductivity in condensed matter physics (Anderson, 1958a, b, 1963): In superconductors, an interior magnetic field is completely excluded due to the Meissner–Ochsenfeld effect. This phenomenon can be understood by the fact that electromagnetic fields acquire a mass and cannot propagate freely inside superconductors (Anderson–Higgs mechanism). Anderson’s argument was based on a nonrelativistic theoretical formalism, but essentially the same thing happens in relativistic field theories.

While the physics of Higgs phenomena has originated from the study of superconductivity, the Higgs mode in superconductors (Pekker and Varma, 2015; Shimano and Tsuji, 2020), which manifests the existence of an effective scalar potential with a Mexican-hat shape (Fig. 1) that causes the Higgs mechanism, has not been observed for a long time. An exception at an early stage was the Raman scattering experiment reported in 1980 for 2H-NbSe₂ (Sooryakumar and Klein, 1980), which is rather a special material in the sense that superconductivity coexists with a charge-density-wave (CDW) order. Only in this particular regime, a resonance peak corresponding to the amplitude mode has been observed in Raman spectra.

In 2013, a coherent long-lived oscillation induced by a mono-cycle terahertz laser pulse was observed for a pure superconductor NbN (“pure” means the one without coexistence of any other long-range orders) (Matsunaga et al., 2013). The oscillation frequency agrees with the superconducting gap energy, implying that the Higgs mode is excited in the terahertz laser experiment. In the subsequent experiment, a multicycle terahertz pulse has been applied to NbN, showing a coherent oscillation with the frequency twice as large as the pump laser frequency (Matsunaga et al., 2014). This is consistent with the fact that the Higgs mode can be generated by a two-photon absorption process through the nonlinear light-Higgs coupling (Tsuji and Aoki, 2015). At the same time, the resonant enhancement of third harmonic generation has been observed in NbN when the superconducting gap coincides with twice the pump frequency (Fig. 2) (Matsunaga et al., 2014). Later, it turns out that impurities play an essential role in the resonant enhancement of third harmonic generation mediated by the Higgs mode (Jujo, 2018; Murotani and Shimano, 2019; Silaev, 2019; Tsuji and Nomura, 2020; Seibold et al., 2021).

Table 1 Examples of phase and amplitude modes in various physical systems.

System	Nambu–Goldstone (phase) mode	Higgs (amplitude) mode	Broken symmetry
Magnet	Magnon	Amplitude mode	Spin rotation
(Incommensurate) Charge density wave	Phason	Amplitudon	Space translation
Superfluid ^4He	Phase mode	–	Phase rotation
Weakly interacting superfluid Bose gas	Phase mode	–	Phase rotation
Strongly interacting superfluid Bose gas in an optical lattice at commensurate filling	Phase mode	Amplitude mode	Phase rotation
Superfluid Fermi gas	Phase mode	Amplitude mode	Phase rotation
Superfluid ^3He (B phase)	Phase mode	Squashing mode	$\text{SO}(3) \times \text{SO}(3) \times \text{U}(1)$
Superconductor	–	Amplitude mode	Phase rotation
Atomic nuclei	Pion	σ Particle	Chiral symmetry
Standard model in high-energy physics	–	Higgs particle	$\text{SU}(2) \times \text{U}(1)$

In the case of superconductors and the standard model in high-energy physics, the system is coupled to gauge fields, and the phase mode disappears due to the Anderson–Higgs mechanism.

If one is not limited to charged systems in which the order parameter is coupled with gauge fields, the phase and amplitude modes of order parameters have been widely observed in symmetry broken phases (see Table 1). For example, magnons, or spin waves, correspond to phase modes in magnetically ordered systems. Liquid helium and cold atomic gases are other examples of physical systems in which collective modes of bosonic and fermionic superfluids are well studied. These collective modes provide important information on the underlying system, such as symmetries, phases, dynamics, and response to external fields.

Throughout the article, we put $\hbar = 1$.

Higgs mode in superconductors

The emergence of collective modes in symmetry broken phases can be understood with a simple macroscopic phenomenological model. For example, the low-energy effective theory of superconductors corresponds to the Ginzburg–Landau (GL) theory, whose Lagrangian density is given, as a functional of a complex scalar field $\psi(\mathbf{r})$ (a “macroscopic wavefunction” of electrons), by

$$\mathcal{L} = - \left[a |\psi(\mathbf{r})|^2 + \frac{b}{2} |\psi(\mathbf{r})|^4 + \frac{1}{2m^*} |(-i\nabla - e^* \mathbf{A})\psi(\mathbf{r})|^2 \right] + c_1 \psi(\mathbf{r})^\dagger (i\partial_t - e^* \phi) \psi(\mathbf{r}) + c_2 |(i\partial_t - e^* \phi) \psi(\mathbf{r})|^2. \quad (1)$$

Here a , b , c_1 , and c_2 are constants; m^* and e^* are effective mass and charge of condensates, and ϕ and $\mathbf{A}$ are scalar and vector potentials for external electromagnetic fields, respectively. The time derivative terms are included phenomenologically. The amplitude of the scalar field $\psi(\mathbf{r})$ serves as an order parameter, and its squared absolute value has a meaning of the superfluid density ($|\psi(\mathbf{r})|^2 = n_s$). The Lagrangian is invariant under the global phase rotation, $\psi \rightarrow e^{i\theta} \psi$. The coefficient a is assumed to behave as $a = a_0(T - T_c)$ ($a_0 > 0$) near the critical point, where T is a temperature of the system, and T_c is a critical temperature at which

superconductivity emerges. At high temperature, the effective potential (the first two terms in the square bracket in Eq. (1)) has a parabolic cylindrical shape with a single minimum at the origin ($\psi = 0$). As the temperature goes down below T_c , the potential turns into a Mexican-hat shape (Fig. 1), where degenerate minima appear along the circle at the bottom of the potential ($|\psi| = \psi_0 > 0$). One of the minima is realized as the ground state, which spontaneously breaks the phase rotation symmetry. Without loss of generality, one can assume that the order parameter takes a real positive value in the ground state.

One can consider fluctuations of the order parameter around the ground state by expanding as

$$\psi(\mathbf{r}) = (\psi_0 + H(\mathbf{r}))e^{i\theta(\mathbf{r})}, \quad (2)$$

where $H(\mathbf{r})$ and $\theta(\mathbf{r})$ represent amplitude and phase fluctuations, respectively. The Lagrangian is then expanded in the following way:

$$\begin{aligned} \mathcal{L} = & 2aH^2 - \frac{1}{2m^*}(\nabla H)^2 - \frac{e^{*2}}{2m^*} \left(A - \frac{1}{e^*} \nabla \theta \right)^2 \\ & \times (\psi_0 + H)^2 - c_1 e^* \left(\phi + \frac{1}{e^*} \partial_t \theta \right) (\psi_0 + H)^2 \\ & + c_2 (\partial_t H)^2 + c_2 e^{*2} \left(\phi + \frac{1}{e^*} \partial_t \theta \right)^2 (\psi_0 + H)^2 \\ & + \dots \end{aligned} \quad (3)$$

The first term indicates that the Higgs mode represented by H has a finite mass, reflecting the fact that the effective potential has a finite curvature along the amplitude direction. The second term in Eq. (3) corresponds to the kinetic term of the Higgs mode. The phase field θ appears without a mass term ($\propto \theta^2$). Hence, θ would be thought of as a massless NG mode. However, θ always appears in the combination of $A - \frac{1}{e^*} \nabla \theta$ or $\phi + \frac{1}{e^*} \partial_t \theta$, due to which one can remove θ by performing a gauge transformation, $A \rightarrow A' = A - \frac{1}{e^*} \nabla \theta$ and $\phi \rightarrow \phi' = \phi + \frac{1}{e^*} \partial_t \theta$ (unitary gauge). By rewriting A' and ϕ' as A and ϕ , one obtains an expression in terms of H ,

$$\begin{aligned} \mathcal{L} = & 2aH^2 - \frac{1}{2m^*}(\nabla H)^2 - \frac{e^{*2}}{2m^*} A^2 (\psi_0 + H)^2 \\ & - c_1 e^* \phi (\psi_0 + H)^2 + c_2 (\partial_t H)^2 + c_2 e^{*2} \phi^2 (\psi_0 + H)^2 \\ & + \dots \end{aligned} \quad (4)$$

The phase mode θ disappears from the expression, and a mass term of the gauge field ($\propto A^2$) appears in the third term. This is nothing but the Anderson–Higgs mechanism. One can count the number of degrees of freedom before and after the Anderson–Higgs mechanism:

$$\begin{aligned} & 2 \text{ (transverse components of } A) + 2 \text{ (real and imaginary parts of } \psi) \\ & \rightarrow 3 \text{ (transverse and longitudinal components of } A) + 1 \text{ (Higgs mode)} \end{aligned}$$

The electromagnetic field, that mediates the long-range Coulomb interaction, screens phase fluctuations of the superconducting order parameter, pushing them up to high energy (in the scale of plasma frequency). As a result of the Anderson–Higgs mechanism, the electromagnetic field itself becomes short-ranged and decays exponentially within the London penetration depth (Meissner–Ochsenfeld effect). The remaining low-energy excitation mode is the Higgs mode. In the vicinity of T_c , however, the phase mode may have a possibility to revive without damping [known as the Carlson–Goldman mode (Carlson and Goldman, 1975)] due to the presence of a large number of normal electrons which screen the long-range Coulomb interaction.

If the system is electrically neutral (i.e., $e^* = 0$), the order parameter is not coupled to gauge fields, and the Anderson–Higgs mechanism does not take place. In this case, the NG mode survives as a massless excitation, which dominates the low-energy behavior. In particular, the Higgs mode can hybridize with the NG mode if $c_1 \neq 0$, which causes a mixing between amplitude and phase modes. In order to decouple the amplitude and phase modes, one often requires an effective particle-hole symmetry, which suppresses the c_1 term and makes the Lagrangian relativistic with an emergent Lorentz symmetry.

In superconductors, there is an approximate particle-hole symmetry at low energy so that one can practically neglect the c_1 term. From Eq. (4), one can see that there is no linear coupling between H and A (or ϕ). This means that the Higgs mode cannot be excited within the linear response regime, which is well expected from the fact that the Higgs mode is a scalar excitation having no electric charge or magnetic moment. On the other hand, if one goes beyond the linear response, the Higgs mode can be excited by electromagnetic fields through the nonlinear coupling (e.g., $\propto A^2 H$) (Tsuji and Aoki, 2015), which has been used to observe the Higgs mode in terahertz laser experiments.

The GL theory does not predict the precise value of the mass of the Higgs mode. It only tells that the mass is proportional to $(-a)^{\frac{1}{2}} \propto (T_c - T)^{\frac{1}{2}}$. From a microscopic theory, the mass is found to coincide with the superconducting gap energy 2Δ . That is, the minimum energy that is required to excite the Higgs mode is the same as the energy to break a single Cooper pair. This causes a problem of using the GL theory in the energy scale of the Higgs mode. In the GL theory, the order parameter is supposed to vary sufficiently slowly in space and time, whereas the order parameter oscillates with the frequency of 2Δ when the Higgs mode is

excited. This already reaches the energy scale of pair breaking, and thus one cannot neglect the effect of quasiparticle excitations, invalidating the basic assumption of the GL description.

The aforementioned issue motivates one to move to a microscopic description of superconductivity, that is, the BCS theory. In the BCS theory, one adopts the Hamiltonian that includes the kinetic energy of electrons and the pairing interaction (usually mediated by phonons),

$$H_{\text{BCS}} = \sum_{\mathbf{k}, \sigma} \varepsilon_{\mathbf{k}} c_{\mathbf{k}\sigma}^\dagger c_{\mathbf{k}\sigma} - \frac{V}{N} \sum_{\mathbf{k}, \mathbf{k}'} c_{\mathbf{k}\uparrow}^\dagger c_{-\mathbf{k}\downarrow}^\dagger c_{-\mathbf{k}'\downarrow} c_{\mathbf{k}'\uparrow}, \quad (5)$$

where $c_{\mathbf{k}\sigma}$ is the annihilation operator of electrons with momentum $\mathbf{k}$ and spin σ , $\varepsilon_{\mathbf{k}}$ is the energy dispersion, $V (> 0)$ is the pairing interaction strength, and N is the number of $\mathbf{k}$ points.

In the mean-field approximation, the Hamiltonian (5) is replaced by $H_{\text{MF}} = \sum_{\mathbf{k}} \Psi_{\mathbf{k}}^\dagger h(\mathbf{k}) \Psi_{\mathbf{k}}$, where $\Psi_{\mathbf{k}} = (c_{\mathbf{k}\uparrow}^\dagger c_{-\mathbf{k}\downarrow}^\dagger)^T$ is the Nambu spinor and

$$h(\mathbf{k}) = \begin{pmatrix} \varepsilon_{\mathbf{k}} & -\Delta^* \\ -\Delta & -\varepsilon_{\mathbf{k}} \end{pmatrix} \quad (6)$$

is the Bogoliubov–de-Gennes Hamiltonian. The off-diagonal element Δ is defined by

$$\Delta = \frac{V}{N} \sum_{\mathbf{k}} \langle c_{\mathbf{k}\uparrow}^\dagger c_{-\mathbf{k}\downarrow}^\dagger \rangle. \quad (7)$$

We assume that Δ takes a real positive value. The eigenvalues of $h(\mathbf{k})$ are found to be $\pm E_{\mathbf{k}} := \pm \sqrt{\varepsilon_{\mathbf{k}}^2 + \Delta^2}$, and thus the single-particle spectrum shows an energy gap of 2Δ . At zero temperature, Δ satisfies the gap equation,

$$\Delta = \frac{V}{N} \sum_{\mathbf{k}} \frac{\Delta}{2E_{\mathbf{k}}}. \quad (8)$$

The dynamics of superconductors is determined by the time-dependent Bogoliubov–de-Gennes equation,

$$i \frac{\partial}{\partial t} \Psi_{\mathbf{k}} = h(\mathbf{k}) \Psi_{\mathbf{k}}. \quad (9)$$

To analyze the equation, it is convenient to introduce Anderson's pseudospins,

$$\sigma_{\mathbf{k}}^\alpha = \frac{1}{2} \langle \Psi_{\mathbf{k}}^\dagger \tau^\alpha \Psi_{\mathbf{k}} \rangle \quad (\alpha = x, y, z). \quad (10)$$

Here τ^α denotes the Pauli matrices. Physically, the x and y components of the pseudospins correspond, respectively, to the real and imaginary parts of Cooper pairs' amplitude $\langle c_{\mathbf{k}\uparrow}^\dagger c_{-\mathbf{k}\downarrow}^\dagger \rangle$, and the z component represents the momentum-dependent occupation of electrons. From Eq. (9), one finds that the time evolution of the pseudospins is given by

$$\frac{\partial}{\partial t} \boldsymbol{\sigma}_{\mathbf{k}} = 2\mathbf{b}_{\mathbf{k}} \times \boldsymbol{\sigma}_{\mathbf{k}}, \quad (11)$$

which resembles the Bloch equation that describes precession motion of spins in a magnetic field. Here $\mathbf{b}_{\mathbf{k}} = (-\text{Re } \Delta, -\text{Im } \Delta, \varepsilon_{\mathbf{k}})$ plays a role of a magnetic field for pseudospins.

In general, the equation of motion (11) becomes a nonlinear equation since it is supplemented by the self-consistency condition (8). However, one can linearize the equation if the deviation from the initial ground state is sufficiently small. By writing $\boldsymbol{\sigma}_{\mathbf{k}}(t) = \boldsymbol{\sigma}_{\mathbf{k}}(0) + \delta\boldsymbol{\sigma}_{\mathbf{k}}(t)$ and $\Delta(t) = \Delta + \delta\Delta(t)$, the linearized equation is expressed as

$$\frac{\partial}{\partial t} \delta\sigma_{\mathbf{k}}^x = -2\varepsilon_{\mathbf{k}} \delta\sigma_{\mathbf{k}}^y, \quad (12)$$

$$\frac{\partial}{\partial t} \delta\sigma_{\mathbf{k}}^y = 2\varepsilon_{\mathbf{k}} \delta\sigma_{\mathbf{k}}^x + 2\Delta \delta\sigma_{\mathbf{k}}^z - \frac{\varepsilon_{\mathbf{k}}}{E_{\mathbf{k}}} \delta\Delta, \quad (13)$$

$$\frac{\partial}{\partial t} \delta\sigma_{\mathbf{k}}^z = -2\Delta \delta\sigma_{\mathbf{k}}^y. \quad (14)$$

By using the relation $\Delta \delta\sigma_{\mathbf{k}}^x = \varepsilon_{\mathbf{k}} \delta\sigma_{\mathbf{k}}^z$, one can further simplify the equation into

$$\frac{\partial^2}{\partial t^2} \delta\sigma_{\mathbf{k}}^x = -4E_{\mathbf{k}}^2 \delta\sigma_{\mathbf{k}}^x + \frac{2\varepsilon_{\mathbf{k}}^2}{E_{\mathbf{k}}} \delta\Delta. \quad (15)$$

After Fourier transformation, one obtains

$$\delta\sigma_{\mathbf{k}}^x(\omega) = \frac{2\varepsilon_{\mathbf{k}}^2}{E_{\mathbf{k}}(4E_{\mathbf{k}}^2 - \omega^2)} \delta\Delta(\omega) \quad (16)$$

Combining with the linearized gap equation, $\delta\Delta(\omega) = \frac{V}{N} \sum_k \delta\sigma_k^x(\omega)$, one finds that a nontrivial solution exists if the following condition is satisfied:

$$\frac{V}{N} \sum_k \frac{2\varepsilon_k^2}{E_k(4E_k^2 - \omega^2)} = 1. \quad (17)$$

This is precisely the condition that has been derived by [Anderson \(1958b\)](#). One can quickly verify that $\omega = 2\Delta$ is a solution of Eq. (17) since it is reduced to the gap equation (8) at this frequency. The solution $\Delta(t)$ consists of a collective amplitude oscillation of the order parameter, and hence is identified to the Higgs mode that has been expected to exist in the GL theory.

Subsequently, the equation of motion for a quench problem has been studied by [Volkov and Kogan \(1974\)](#), who showed that the amplitude oscillation of the gap function does not persist but decays in a power law as

$$\Delta(t) \sim \Delta + \frac{c}{\sqrt{2\Delta t}} \cos(2\Delta t + \varphi) \quad (18)$$

with certain constants c and φ . This slight instability (power-law decay) of the Higgs mode is related to the fact that the energy of the Higgs mode lies right at the bottom edge of the quasiparticle excitation continuum. The decay into quasiparticles occurs without collisions, similar to the case of Landau damping for plasma waves. The energy dispersion of the Higgs mode at finite momentum, $\omega_H(q)$, has the following form ([Littlewood and Varma, 1982](#)),

$$\omega_H(q) = \sqrt{(2\Delta)^2 + \frac{1}{3}v_F^2q^2} - i\frac{\pi^2}{24}v_Fq, \quad (19)$$

where v_F is the Fermi velocity and $q = |q|$. The presence of the imaginary part indicates that the Higgs mode has a finite lifetime at finite q due to the decay into quasiparticles. Especially, the mode becomes overdamped when $v_Fq/\Delta \gtrsim 1$.

In multiband superconductors, the system may possess multiple order parameters (multigap superconductors) such as MgB_2 . In this case, there can arise a collective oscillation of the relative phase between two order parameters, known as the Leggett mode ([Leggett, 1966](#)). Since the relative phase oscillation does not induce the net current and hence does not couple to gauge fields linearly, the Leggett mode can evade the Anderson–Higgs mechanism, remaining to survive at low energy.

If there is a hidden competing order that stays close to the primary order, the so-called Bardasis–Schrieffer mode can emerge as a collective oscillation of the amplitude of the secondary order parameter ([Bardasis and Schrieffer, 1961](#)). For example, some of iron-based superconductors are expected to have a close competition between the $s_{\pm}$ pairing ground state with the d -wave pairing instability. The Bardasis–Schrieffer mode can be used to probe such hidden instabilities that are difficult to detect by other means.

In strongly correlated systems, one may need to go beyond the BCS theory and take into account quantum correction effects to treat Higgs modes, which can be defined by the peak of the superconducting amplitude-amplitude correlation function. It is expected that the lifetime (i.e., inverse of the peak width) of the Higgs mode would become shorter and shorter as one goes into strongly correlated regimes due to the decay to quasiparticles, and the amplitude oscillation of the order parameter would become overdamped at some point. Such kind of behavior has been observed in the ordered phase of the Hubbard model with an interaction quench ([Werner et al., 2012](#); [Tsui et al., 2013](#)).

Higgs modes in atomic Fermi gases

The Higgs mode appears not only in superconductors but also in neutral fermionic superfluids. The only traditional condensed-matter system that falls into the latter category had been the system of superfluid ^3He . In the last few decades, a new system arose in the field of atomic physics: Superfluidity in a dilute gas of fermionic atoms has been realized in 2004 ([Regal et al., 2004](#); [Zwierlein et al., 2004](#)). Since then, this system has been offering a unique opportunity for studying Higgs modes in fermionic superfluids.

Atomic gases have several advantages over solid-state systems. One of them is high controllability of system parameters. Using experimental techniques developed in atomic, molecular, and optical physics, various parameters can be tuned with unprecedented precision. In atomic Fermi gases, the interaction strength between fermions can be tuned by external fields via the Feshbach resonance. Employing this technique, one can observe a smooth crossover between the BCS-type state with large overlapping Cooper pairs and Bose–Einstein condensation (BEC) of tightly bound molecules of two fermions, known as the “BEC-BCS crossover,” which has been realized also in 2004 ([Regal et al., 2004](#); [Zwierlein et al., 2004](#)). This phenomenon had never been directly observed in condensed-matter systems, though it was theoretically speculated by [Leggett \(1980\)](#) and [Eagles \(1969\)](#). This experimental progress allows one to study the evolution of the Higgs mode in the BEC-BCS crossover.

The interaction strength in this system is often described by the dimensionless parameter $1/(k_F a)$, where k_F and a are the Fermi wave number and the s -wave scattering length, respectively. The s -wave scattering length can be tuned by an external magnetic field due to the Feshbach resonance. The weak-coupling BCS regime and strong-coupling BEC regime correspond to $1/(k_F a) < 0$ and $1/(k_F a) > 0$, respectively. The crossover between the BCS and BEC physics occurs at the unitary limit $1/(k_F a) = 0$, at which a diverges.

The Higgs mode in a superfluid Fermi gas of ^6Li atoms has been observed in 2018 ([Behrle et al., 2018](#)). A novel scheme to induce the Higgs mode has been developed in the experiment: One of the two hyperfine states involved in pairing is coupled with an initially unoccupied third state by a radiofrequency field. In this manner, a periodic modulation of the amplitude of the gap

Fig. 3 Measured excitation spectra of the Higgs mode in a superfluid Fermi gas for different interaction strength $1/(k_F a)$. Adapted from Behrle A, Harrison T, Kombe J, Gao K, Link M, Bernier J-S, Kollath C, and Köhl M (2018) Higgs mode in a strongly interacting fermionic superfluid. *Nature Physics* 14(8): 781–785. ISSN 1745-2481

function was induced. The Higgs mode was searched by rapidly sweeping the magnetic field onto the molecular side of the Feshbach resonance and measuring the energy absorption spectrum. The excitation spectra in Fig. 3 show the clear resonance at 2Δ in the BCS side ($1/(k_F a) < 0$) while the peak broadens significantly signaling the instability of the Higgs mode in the BEC side ($1/(k_F a) > 0$).

The time-dependent Bogoliubov–de-Gennes (tdBdG) formalism has been extensively used to study the dynamical properties of superfluid Fermi gases. In this formalism, the gap function $\Delta(\mathbf{r}, t)$ obeys the tdBdG equation

$$i \frac{\partial}{\partial t} \begin{pmatrix} u_v(\mathbf{r}, t) \\ v_v(\mathbf{r}, t) \end{pmatrix} = \begin{pmatrix} \hat{h} & \Delta \\ \Delta^* & -\hat{h} \end{pmatrix} \begin{pmatrix} u_v(\mathbf{r}, t) \\ v_v(\mathbf{r}, t) \end{pmatrix}, \quad (20)$$

where $\hat{h} = -\nabla^2/2m + U(\mathbf{r}) - \mu$, m is the atomic mass, μ is the chemical potential, $U(\mathbf{r})$ is the trapping potential, v is the index for the eigenstates, and u_v and v_v are the time-dependent quasi-particle amplitudes, respectively. The tdBdG equation needs to be solved self-consistently with the gap equation,

$$\Delta(\mathbf{r}, t) = \frac{V}{N} \sum_v u_v(\mathbf{r}, t) v_v^*(\mathbf{r}, t), \quad (21)$$

and the equation for the total number of atoms $\mathcal{N}$,

$$\mathcal{N} = 2 \int d\mathbf{r} \sum_v |u_v(\mathbf{r}, t)|^2. \quad (22)$$

In a uniform system ($U(\mathbf{r}) = 0$), substituting the static solution of Eq. (20) $u_k^2 = (1 + \varepsilon_k/E_k)/2$ and $v_k^2 = (1 - \varepsilon_k/E_k)/2$ ($\varepsilon_k = k^2/2m - \mu$ and $E_k = \sqrt{\varepsilon_k^2 + \Delta^2}$) into Eqs. (22) and (22), the former reduces to the gap equation (8), while the latter reduces to

$$\mathcal{N} = \sum_k \left(1 - \frac{\varepsilon_k}{E_k} \right). \quad (23)$$

The self-consistent solution of (Δ, μ) for the gap equation (8) and the number equation (23) smoothly connects the weak-coupling BCS limit with $((8\varepsilon_F/e^2)e^{-\pi/2k_F|a|}, \varepsilon_F)$ and the strong-coupling BEC limit with $(\sqrt{16/3\pi}|\mu|^{1/4}\varepsilon_F^{3/4}, -1/2ma^2)$, where e is Napier's constant and ε_F is the Fermi energy. Note that μ coincides with the binding energy of molecules in the BEC limit. The above tdBdG formalism thus correctly captures the dynamical properties of a superfluid Fermi gas including the Higgs mode throughout the entire BEC-BCS crossover.

One can study small amplitude oscillations of the gap function (Higgs mode) induced by a quench of the interaction strength in the tdBdG formalism. The gap function evolves in time according to Eq. (18) in the BCS regime, where the amplitude oscillates with the frequency $\omega_H = 2\Delta$ and the oscillation decays in a power law ($\sim t^\gamma$) with the exponent $\gamma = -1/2$ (Volkov and Kogan, 1974). In the BEC regime, on the other hand, the frequency $\omega_H = 2\sqrt{\Delta^2 + \mu^2}$ and the exponent of the power-law decay $\gamma = -3/2$ for the amplitude oscillation have been predicted (Gurarie, 2009). The former coincides with twice of the energy threshold for the creation of fermionic excitations by pair-breaking. The evolution of the frequency ω_H and the power γ through the BEC-BCS crossover is of particular interest and worth investigating in future experiments (Tokimoto et al., 2019).

The NG mode has also been investigated in atomic fermi superfluids. It manifest itself as the Anderson–Bogoliubov (AB) phonon (phase) mode as shown in Table 1. Anderson predicted the sound velocity $c = v_F/\sqrt{3}$ for the AB phonon mode in the BCS limit by the generalized random-phase approximation (Anderson, 1958b). The evolution of the excitation spectra throughout the BEC-BCS crossover has been studied using two-photon Bragg spectroscopy, which allows characterization of the dispersion relation of the AB phonon mode (Hoinka et al., 2017).

Higgs and Nambu–Goldstone modes in other systems

The NG and Higgs modes exist ubiquitously in quantum many-body systems that possess both a spontaneously broken continuous symmetry and an approximate particle-hole symmetry. In the previous sections, we have taken superconductors and superfluid states of ultracold two-component Fermi gases as specific examples that possess either or both of the NG and Higgs modes. In this section, we explain several other significant examples of the NG and Higgs modes in the contexts of condensed matter and ultracold-atom physics in order to illustrate broad applicability of the concepts.

We first consider a superfluid state of ultracold spinless Bose gases in optical lattices. An optical lattice means a periodic potential for atoms that is created by two counter-propagating laser beams. When the optical lattice potential is sufficiently deep, the system is well described by the Bose–Hubbard model,

$$\hat{H}_{\text{BH}} = -J \sum_{\langle j,l \rangle} (\hat{b}_j^\dagger \hat{b}_l + \text{h.c.}) + \frac{U}{2} \sum_j \hat{b}_j^\dagger \hat{b}_j \hat{b}_j^\dagger \hat{b}_j + \sum_j (\varepsilon_j - \mu) \hat{b}_j^\dagger \hat{b}_j, \quad (24)$$

where $\hat{b}_j$, U , J , and μ denote, respectively, the annihilation operator of bosons at site j , the onsite interaction, the hopping, and the chemical potential. The external field potential ε_j is present for trapped atoms in standard experiments. In Fig. 4, we show a ground-state phase diagram of the homogeneous Bose–Hubbard model in the $(ZJ/U, \mu/U)$ plane, where Z is the coordination number. When the filling factor, which is the number of particles per lattice site, is integer and ZJ/U is small, the ground state is a Mott insulating (MI) state. Otherwise, it is a superfluid state. There is a continuous quantum phase transition from the MI to the

Fig. 4 Ground-state phase diagram of the homogeneous Bose–Hubbard model obtained by using a mean-field theory. The gray shaded areas near the Mott insulator (MI) regions roughly mark the regions where the superfluid (SF) order parameter is small enough for the fourth-order GL approximation (i.e., the effective action can be written by the expansion up to fourth order in the order parameter) to be valid. On the dashed lines in the SF region, the effective particle-hole symmetry is present. n denotes the filling factor. Adapted from Nakayama T, Danshita I, Nikuni T, and Tsuchiya S (2015) Fano resonance through Higgs bound states in tunneling of Nambu–Goldstone modes. *Physical Review A* 92(4): 043610

superfluid state, where the $U(1)$ symmetry is spontaneously broken. In the superfluid region near the quantum phase transitions, which is the *gray-shaded area* in Fig. 4, low-energy properties of the system can be effectively described by the GL theory (Sachdev, 2011). At the tip of the lobe of the Mott insulating region, where the quantum phase transition to a superfluid with commensurate filling occurs, there emerges particle-hole symmetry. In the nearby superfluid state at the commensurate filling, the emergent particle-hole symmetry survives approximately so that the effective theory coincides with the Lagrangian of Eq. (1) with $e^* = 0$. Consequently, the Higgs mode is present as an approximately independent collective mode. Note that there is no Higgs mode in a bosonic superfluid state without particle-hole symmetry as in the cases of superfluid ^4He and Bose–Einstein condensates of weakly-interacting atomic Bose gases. When Z/U decreases toward the critical value $(Z/U)_c$, the energy gap of the Higgs mode Δ_g approaches zero as $\Delta_g \propto |z/U - (z/U)_c|^\nu$, where ν is the critical exponents for the correlation length of the $(D + 1)$ -dimensional classical XY model and D denotes the spatial dimension of the system.

In 2012, Endres et al. have investigated dynamics of two-dimensional gas of ^{87}Rb atoms (bosons) in optical lattices in response to the temporal modulation of the lattice depth in order to measure the gap of the Higgs mode (Endres et al., 2012). Fig. 5B shows the temperature of the system after the application of the lattice modulation as a function of the modulation frequency for the superfluid state at $J/J_c = 1.2$, where J_c is the transition value of the hopping for a given U at unit filling. Above an onset frequency ν_0 , the response exhibits a broad spectrum. Quantitative comparisons with theoretical analyses have revealed that the onset frequency (Fig. 5A) coincides with the gap of the Higgs mode at zero momentum. It is worth noticing that the Higgs mode has not been observed as a resonance peak in the response. This smearing of the resonance can be attributed to combined effects of the spatial inhomogeneity due to the trapping potential and the finite temperatures (Pollet and Prokofev, 2012).

We next consider antiferromagnetic materials consisting of dimers of $S = 1/2$ spins, such as TiCuCl_3 (Rüegg et al., 2008) and KCuCl_3 (Kuroe et al., 2012), which can be effectively described by the following Hamiltonian,

$$\hat{H}_{\text{AFD}} = \sum_j \left(\hat{S}_{j,R} \cdot \hat{S}_{j,L} - J_{xx} \hat{S}_{j,R}^x \hat{S}_{j,L}^x \right) + \sum_{j,l;m,m'} J_{j,l;m,m'} \hat{S}_{l,m} \cdot \hat{S}_{j,m'}. \quad (25)$$

Here, $\hat{S}_{j,m} = (\hat{S}_{j,m}^x, \hat{S}_{j,m}^y, \hat{S}_{j,m}^z)$ denotes the $S = 1/2$ spin operator at spin $m (= L, R)$ of dimer j . $J(> 0)$, $J_{xx}(> 0)$ and $J_{j,l;m,m'}$ are the intradimer isotropic interaction, the intradimer anisotropic interaction, and the interdimer isotropic interaction, respectively. In Fig. 6, the spatial configuration of the interdimer interactions is illustrated (Matsumoto et al., 2004). To be concrete, we hereafter focus on the case of TiCuCl_3 , in which the Higgs mode has been observed via neutron scattering experiments. In this case, the most dominant interdimer interaction is J_2 that is antiferromagnetic. Although J_{xx} is about 1% of J , it is important for discussing the NG and Higgs modes in the sense that it reduces the spin rotation symmetry from $SU(2)$ to $U(1)$.

At atmospheric pressure, J is dominant over J_2 so that the low-temperature magnetic state is a dimerized state in that two spins on each dimer form a spin singlet and there is no magnetic order. When the hydrostatic pressure p is increased, J_2/J increases and a continuous quantum phase transition to an antiferromagnetic ordered state occurs at $p = p_c \simeq 1.08$ kbar. Associated with the

Fig. 5 Experimental observation of the Higgs gap in the system of ultracold Bose gases in optical lattices. (A) Excitation gap versus the hopping parameter j , which is denoted by J in the main text, in unit of its critical value j_c . Solid line and dashed line, respectively, stand for the Higgs and Mott gaps calculated by the Gutzwiller mean-field theory for a homogeneous system with unit filling. (B) Temperature response to temporal modulation of the lattice depth for three values of j/j_c . transition, the spin-rotation symmetry is spontaneously broken. The quantum phase transition can be qualitatively captured by a mean-field approximation in which the many-body wave function is assumed to be a product state,

$$|\Psi_{\text{MF}}\rangle = \bigotimes_j |\phi\rangle_j \quad (26)$$

where

$$|\phi\rangle_j = a_{j,0}|s\rangle_j + a_{j,1}|t_1\rangle_j + a_{j,2}|t_2\rangle_j + a_{j,3}|t_3\rangle_j. \quad (27)$$

The local state at dimer j is spanned by the spin-singlet and triplet states, namely, $|s\rangle = 2^{-\frac{1}{2}}(|\uparrow, \downarrow\rangle - |\downarrow, \uparrow\rangle)$, $|t_1\rangle = 2^{-\frac{1}{2}}(|\uparrow, \downarrow\rangle + |\downarrow, \uparrow\rangle)$, $|t_2\rangle = 2^{-\frac{1}{2}}(|\uparrow, \uparrow\rangle + |\downarrow, \downarrow\rangle)$, and $|t_3\rangle = 2^{-\frac{1}{2}}(|\uparrow, \uparrow\rangle - |\downarrow, \downarrow\rangle)$. The coefficients satisfy the normalization condition $\sum_{\alpha=0}^3 |a_{j,\alpha}|^2 = 1$. In the limit of $J_{j,l;m,m'} \rightarrow 0$, the four states are the eigenstates of each local Hamiltonian, where $|s\rangle$ is the ground state, $|t_1\rangle$ and $|t_2\rangle$ are the degenerate first excited states, and $|t_3\rangle$ is the highest energy state. When J_2/J is finite but smaller than the critical value, the ground state remains to be $|\phi\rangle = |s\rangle$ for all the dimers and there is the energy gap to create triplet states. The energy cost for creating $|t_1\rangle$ is equivalent to that for creating $|t_2\rangle$ so that this symmetry can be regarded as a particle-hole symmetry. At the critical value of J_2/J , the energy gap closes. When J_2/J increases further, the coefficients $a_{j,\alpha}$ for $\alpha = 1, 2, 3$ become finite and the antiferromagnetic order emerges. The low-energy properties in the ordered phase can be effectively described by the GL theory of Eq. (1), thanks to the spontaneous breaking of the $U(1)$ symmetry and the presence of the particle-hole symmetry. Hence, there are the NG and Higgs modes in the ordered phase. In addition, there is another gapped mode that dominantly includes the $|t_3\rangle$ excitation.

In 2008, Rüegg et al. have observed the excitation modes explained above by means of inelastic neutron scattering (Rüegg et al., 2008). Fig. 7 shows the energy gaps of the excitation modes at specific momenta, which are detected as resonance peaks in the spectra of inelastic neutron scattering. In the dimerized phase at low pressure, there are three gapped modes corresponding to the creation of a triplet excitation. The gap of the two modes (blue symbols) closes at the quantum critical point whereas that of the other mode (black symbols) remains gapped. In the antiferromagnetic ordered phase at high pressure, the former two modes transform into the Higgs and NG modes, which correspond to longitudinal and transverse fluctuations of the magnetic order parameter.

In the last place, we briefly mention another important example, namely, materials with incommensurate CDW (ICDW) order (Grüner, 1988). Specifically, in solid-state materials with quasi-1D lattice structure, such as $2H\text{-NbSe}_2$ (Tsang et al., 1976) and $\text{K}_{0.3}\text{MoO}_3$ (Yusupov et al., 2010), electron–phonon interactions induce the condensation of particle-hole pairs with momenta $2k_F$ and $-2k_F$, leading to the formation of ICDW states at low temperatures. In the ICDW state, the electron density is given by

$$\rho(x) \simeq \rho_0 + \rho_1 \cos(2k_F x + \varphi), \quad (28)$$

where k_F , ρ_0 , ρ_1 , and φ denote, respectively, the Fermi momentum, the average electron density, the amplitude, and the phase of ICDW. The oscillation of the amplitude ρ_1 , which is often called amplitudon, corresponds to the Higgs mode whereas that of the phase φ (phason) does to the NG mode. The Higgs mode has been observed in several ICDW materials via Raman spectroscopy.

Conclusion

We have reviewed various order-parameter dynamics that appear in condensed matter systems. Especially, we have focused on Higgs and Nambu–Goldstone (NG) modes, corresponding to amplitude and phase oscillations of order parameters. They provide important information on the fundamental properties of underlying quantum many-body systems, including symmetries, phase transitions, dynamics, and response to external perturbations. Target systems range from superconductors to cold-atom systems (bosonic and fermionic superfluids), quantum magnets, charge density waves, and so on. Here one can see the universality of

Fig. 7 Energy gaps of the magnetic excitations in TiCuCl_3 versus pressure, which has been detected via inelastic neutron scattering. The *red symbols* correspond to the gap of the Higgs mode in the ordered phase, namely, the renormalized classical antiferromagnetic (RC-AFM) phase. QD and QCP stand for the quantum disordered phase and quantum critical point, respectively. p_c , L, and T denote the critical pressure, longitudinal magnetic excitation, and transverse magnetic excitation, respectively. (0 4 0) or (0 0 1) means the value of the momentum transfer in the neutron scattering. Adapted from Rüegg C, Normand B, Matsumoto M, Furrer A, McMorro DF, Krämer KW, Güdel HU, Gvasaliya SN, Mutka H, and Boehm M (2008) Quantum magnets under pressure: Controlling elementary excitations in TiCuCl_3 . *Physical Review Letters* 100(20): 205701

order-parameter dynamics, which may not depend so much on details of the system, partly because they are effectively described by a “common language” based on quantum field theories at low energies.

There are many open issues that remain to be addressed. In the case of superconductors, it is experimentally important to understand various aspects of Higgs modes in superconductors, especially for those beyond NbN and the coexisting phase of CDW and superconductivity in NbSe_2 . The difficulty lies in the fact that there are always competitions between the Higgs mode and quasiparticle excitations (Cea et al., 2016), both of which have similar characters with respect to symmetries and excitation energies. To distinguish them, one has to carefully compare experimental results with theoretical calculations, which may depend on details of materials, impurities, electron–phonon couplings, and so on (Tsuji and Nomura, 2020). This reflects the situation that one has not fully understood the universal (i.e., material-independent) condition that the Higgs mode becomes visible in experiments. To see enriched order-parameter dynamics, it will be fascinating to extend the observation of Higgs modes in various multiband superconductors such as MgB_2 (Kovalev et al., 2021) and unconventional superconductors (Schwarz et al., 2020) such as cuprates (Barlas and Varma, 2013; Katsumi et al., 2018; Chu et al., 2020) and iron-based superconductors (Vaswani et al., 2021; Grasset et al., 2022). A potential application of the Higgs mode includes detection of light-induced orders (Isoyama et al., 2021; Katsumi et al., 2022) and hidden fluctuations (Katsumi et al., 2020).

In the case of cold-atom systems, further investigations, both experimentally and theoretically, are needed to better understand the evolution of the Higgs modes across the BCS-BEC crossover in a superfluid fermi gas and the SF-MI phase transition in a bosonic superfluid in an optical lattice. In the lattice-boson systems, in particular, it is a long-standing problem whether or not the Higgs mode can be detected as a resonance peak in the response to temporal modulation of an external potential. Since recent experiments on optical-lattice systems have realized almost homogeneous samples of ultracold gases (e.g., Mazurenko et al., 2017), it will be interesting to experimentally address such a problem. Last but not least, taking advantage of the high degree of ability to control the system, it may be worthwhile to investigate previously unexplored aspects of Higgs modes, such as tunneling properties (Nakayama et al., 2015; Nakayama and Tsuchiya, 2019), which are typically difficult to study in solid-state systems.

Abstract

Many superfluid and superconducting systems can be well characterized by a complex order parameter that obtains a nonzero expectation value after spontaneous $U(1)$ symmetry breaking. The complex order parameter can exhibit oscillations in phase or in amplitude, corresponding to Goldstone and Higgs excitations, respectively. These modes are also expected to be present in superfluid atomic Bose and Fermi gases. The excellent level of experimental control over interaction strength, atom numbers, and trapping geometry motivated theoretical and experimental efforts to study the Goldstone and Higgs modes in these cold atom systems. In atomic Fermi superfluids in particular, there exists a tunable coupling between these modes, as well as a coupling to a nearby continuum of single-particle excitations, and this leads to a much richer physics than can be initially expected from simple field-theoretical models. In this contribution, the recent theoretical and experimental developments for the collective modes in superfluid atomic systems are reviewed and placed in the context of earlier research both in particle physics and solid-state physics. The focus is on superfluid Fermi gases, as they include the case of the Bose gas in the limit of strong pairing. For this system, the state-of-the-art theoretical understanding of these modes is provided and compared to recent experimental observations of the collective modes.

Introduction

Collective modes of many-body quantum systems are crucial ingredients in the description of the low-temperature dynamics and thermodynamics of these systems. They allow to construct simplified models for many phenomena, based on fewer and more weakly interacting constituents than those of the original many-body system. Very often, these modes also reveal emergent properties not easily understood from the viewpoint of the original building blocks of the system.

Here, we focus on collective modes arising from spontaneously breaking a continuous symmetry. The paradigmatic example that we will explore in more detail is the case of a complex scalar order parameter¹, for which the $U(1)$ symmetry can be spontaneously broken. This is up to now also the most relevant case in cold atom systems, both for Bose gases where the order parameter represents the macroscopic wave function of the condensate, and for superfluid Fermi gases where the order parameter corresponds to the wave function characterizing the pair condensate. In both cases, we will denote the order parameter by $\Psi(\mathbf{r}, t)$.

When the $U(1)$ symmetry is spontaneously broken, collective modes of the order parameter appear (for an excellent review, see [Pekker and Varma \(2015\)](#)). One mode is associated to the modulation of the phase of the order parameter. Since any choice of phase is equivalent by the $U(1)$ symmetry, any modulation in the phase in the symmetry-broken phase should have an energy tending to zero as its wavelength tends to infinity. This gapless mode was described by [Nambu \(1960\)](#), and later refined by

¹Superfluid Helium-3 is an example of a system with a more complicated order parameter, and hence more collective modes.

Goldstone (1961), in the context of particle physics. From this, it got its name the “Goldstone mode.” In the context of condensed matter physics, more precisely superconductivity, this mode had already been identified earlier by Bogoliubov et al. (1958) and Anderson (1958a), who also realized that for a charged system, the Goldstone mode acquires a gap (Anderson, 1958b). However, in the context of quantum gases, the mode is gapless, since the system consists of neutral atoms. Within the quantum gas community, this mode is most commonly referred to as the “Anderson–Bogoliubov mode.”

The complex order parameter is characterized by phase and amplitude, so besides the gapless Goldstone mode, there is also a mode associated with oscillations of the modulus of the order parameter, commonly called the “Higgs” mode. In particle physics, this mode plays an important role, as pointed out by Higgs (1964) and Englert and Brout (1964), who based themselves on an observation by Anderson (1963) on plasma oscillations. In the context of the standard model, the order parameter is associated to the condensate a new quantum field invoked to generate the masses of the gauge bosons. At first, condensed matter physics did not take much note of the standard model Higgs mode. It was not until the detection of the amplitude mode in superconductors by Sooryakumar and Klein (1980) and the subsequent theoretical description (Littlewood and Varma, 1981, 1982) for the case of superconductors that the concept of a Higgs mode came fully to the attention of the condensed matter community. Most recently, the advent of ultracold quantum gases with their exquisite experimental controllability and tunability has spurred a renewed interest in the Higgs/amplitude and Goldstone/Anderson–Bogoliubov modes in superfluid systems.

Before we discuss the realizations of these modes in atomic gases in the next sections, there are a few important remarks to be made about the difference with their particle physics counterparts. A well-known graphical depiction of the Higgs field is that of the Mexican hat potential. The Goldstone mode follows the valley, whereas the Higgs mode is a radial oscillation up and down the hat’s rim. An objection to this graph, from the point of view of Fermi superfluids and superconductors, is that it seems to suppose that the (free) energy as a function of the order parameter can be expanded in series around its value in the normal (nonsuperfluid) state, which is not the case, in contrast to the standard model Higgs field where the Mexican hat potential is assumed from the start. Another difference, as noted in Pekker and Varma (2015), is that the original Higgs theory is a locally gauge invariant theory, which need not be the case for realizations in atomic gases. Moreover, in contrast to the field theoretical counterpart, the Higgs mode in Fermi superfluids lies inside the continuum of pair-breaking excitations and is strongly influenced by it. A final point to keep in mind, and that will be discussed in more detail below, is that the phase and amplitude modes are in general coupled in superfluid gases, so the eigenmodes have a mixed nature and may even become degenerate—even in the presence of a Mexican hat potential. To decouple these modes, one needs exact particle–hole symmetry, which is not present in general. It can be realized only in special cases: in the Bardeen–Cooper–Schrieffer (BCS) limit of a fermionic superfluid, or by fine-tuning a system in an optical lattice.

Collective modes in Bose condensates

Bose–Einstein condensates (BEC) in cold atomic gases are characterized by a complex scalar order parameter $\Psi(\mathbf{r}, t)$ that obeys the Gross–Pitaevskii equation (see Pitaevskii and Stringari, 2003),

$$i\hbar \frac{\partial \Psi}{\partial t} = -\frac{\hbar^2}{2m} \nabla^2 \Psi + V\Psi + g|\Psi|^2\Psi, \quad (1)$$

where m is the mass of the atoms, V is an external potential, and g denotes the strength of the contact potential, related to the s-wave scattering length between the atoms. This equation describes condensates well for temperatures sufficiently below the critical temperature so that effects of thermal excitations are negligible. The description in terms of the order parameter neglects quantum fluctuations of the Bose field, which is justified when the bosons macroscopically occupy a single mode. The order parameter is interpreted straightforwardly: its modulus squared $|\Psi|^2$ represents the density n of Bose condensed atoms, and its phase θ is related to the velocity field through $\mathbf{v} = (\hbar/m)\nabla\theta$.

This equation does not allow for uncoupled phase and amplitude modes; the only collective mode (in the uniform system, $V = 0$) is the Bogoliubov mode with dispersion

$$\omega = ck\sqrt{1 + \frac{1}{2}(k\xi)^2}, \quad (2)$$

where $c = \sqrt{gn/m}$ is the sound velocity, and $\xi = \sqrt{\hbar^2/(2mgn)}$ is the healing length of the condensate (Pitaevskii and Stringari, 2003). This can be considered as the Goldstone mode of the condensate, and no separate Higgs mode exists. In the long wavelength limit ($k \rightarrow 0$), the mode turns to a sound mode. As the wave number of the mode grows to become comparable to the healing length $k\xi \gtrsim 1$, the mode no longer represents a collective oscillation. Rather it becomes a single-particle excitation, taking an atom out of the condensate and into the normal-state cloud.

The Bogoliubov sound mode was observed experimentally, shortly after the first realization of BEC in cold trapped gases, by modulating the trapping potential to excite these modes (Jin et al., 1996; Andrews et al., 1997). A more refined technique to probe this excitation is through Bragg spectroscopy, where a fixed amount of energy at a fixed wavelength can be imparted on the condensate via two crossed laser beams, as the condensate absorbs a photon from one beam and emits it in the other. This technique reveals the structure factor, in which the Bogoliubov modes were characterized (Stamper-Kurn et al., 1999).

As mentioned above, the amplitude mode is not independently present in uniform BECs (nor in the case of a trapping potential that varies slowly with respect to the healing length). However, condensates can be placed in optical lattices, realizing the Bose–Hubbard model, and allowing both the nearest-neighbor hopping amplitude J and the on-site interaction U to be tuned experimentally. Huber et al. (2007) have shown that along certain curves in the J – U phase diagram, particle–hole symmetry is restored. In the superfluid phase, this leads to the existence of gapped amplitude modes. These were subsequently discovered experimentally, again using Bragg scattering, by Bissbort et al. (2011). Following theoretical work (Podolsky et al., 2011; Pollet and Prokofiev, 2012), that showed that the amplitude mode is also present in a two-dimensional optical lattice, the amplitude mode was excited and observed in two-dimensional systems by modulating the lattice depth (Endres et al., 2012), or by Bragg spectroscopy using two crossed optical cavities (Léonard et al., 2017).

So, in summary, for cold atomic Bose gases, the Bogoliubov (Goldstone) mode is easily accessible by disturbing and probing the condensate density, but the amplitude (Higgs) mode has to be engineered into the system, by using optical lattices. The study of the Higgs mode and its visibility in quantum simulations of the Bose–Hubbard model has been the subject of a large amount of theoretical work that would require a much longer review paper than this encyclopedia entry. Instead, and for the remainder of this paper, we turn to superfluid Fermi gases. Superfluid Fermi gases are the neutral counterpart of superconductors, and they are most relevant to link the cold atomic systems to solid-state physics in general and superconductors in particular. Moreover, as will be discussed below, the interaction strength between the fermionic atoms can be tuned, and the case of a condensate of point bosons is retrieved in the limit of tightly bound pairs.

Order parameter for the superfluid Fermi gas

In atomic Fermi gases, superfluidity requires the presence of pairing between the atoms. The pairing partners are typically different hyperfine states of a given fermionic isotope; for the sake of simplicity we will refer to the two pairing states as “spin-up” and “spin-down.” At low temperatures (such that the de Broglie wavelength is much larger than the range of the interatomic potential) scattering between atoms is dominated by the s-wave channel, and fully characterized by the s-wave scattering length a_s . For fermionic atoms, the requirement of antisymmetry precludes s-wave interactions between same spin atoms.

Pairing between ultracold, neutral atoms was first investigated theoretically in the framework of BCS theory by Houbiers and Stoof (1999). In the conventional BCS model, the parameter that controls the strength of the pairing is the inverse product of the BCS interaction strength with the density of states at the Fermi level. In (three-dimensional) cold Fermi gases, this parameter is replaced by $1/(k_F a_s)$, with k_F , the Fermi wave number. Remarkably, the s-wave scattering length a_s can be tuned experimentally using Feshbach resonances. These are scattering resonances between a bound state in a closed scattering channel, and the scattering state of colliding atoms in the open channel. Here, these channels are characterized by different hyperfine states so that the resonance can be tuned via an external magnetic field through the Zeeman effect. This allows to enhance the strength of the attractive interaction (and raise the critical temperature), by making a_s more strongly negative. As the bound state of the closed channel dips below the scattering energy (and a_s becomes positive), the bound molecular state mixes with the scattering state, and allows for a BEC of strongly bound molecules. Experimentally, the BEC–BCS crossover region ($1 \gtrsim 1/(k_F a_s) \gtrsim -1$) is entirely accessible, including the unitary limit ($1/(k_F a_s) = 0$). This results in a much richer physics than for the limiting case of a BEC discussed in the previous section.

The order parameter $\Psi(\mathbf{r}, t)$ now represents the pair condensate. To see what that means, we turn to the path integral formalism, and start from the imaginary time action functional S for the Fermi gas described by Grassmann variables ψ_σ for fermions with spin σ :

$$S = \int_0^\beta d\tau \int d\mathbf{r} \left[\sum_\sigma \bar{\psi}_\sigma \left(\partial_\tau - \frac{1}{2m} \nabla_{\mathbf{r}}^2 - \mu_\sigma \right) \psi_\sigma + g \bar{\psi}_\uparrow \bar{\psi}_\downarrow \psi_\downarrow \psi_\uparrow \right], \quad (3)$$

where we have set $\hbar = k_B = 1$, and $\beta = 1/k_B T$ represents the inverse temperature. The chemical potentials for each spin species μ_σ can in principle be set independently. The interaction strength g is related to the scattering length a_s via the renormalization relation

$$\frac{1}{g} = \frac{m}{4\pi a_s} - \int_{k < k_c} \frac{d^3 k}{(2\pi)^3} \frac{m}{k^2}. \quad (4)$$

The complex order parameter for the pair superfluid can then be interpreted as arising from a Hubbard–Stratonovich auxiliary field introduced to decouple the interaction term and integrate out the fermionic degrees of freedom. The Hubbard–Stratonovich identity allows to transform the fermionic action into an equivalent effective bosonic action for the fermionic pairs such that the functional integral over this field yields the same partition sum

$$\mathcal{Z} = \int \mathcal{D}\psi \exp\{-S[\psi]\} = \int \mathcal{D}\Delta \exp\{-S_{\text{eff}}[\Delta]\}, \quad (5)$$

with

$$S_{\text{eff}} = \int_0^\beta d\tau \int d\mathbf{r} \frac{|\Delta_{\mathbf{r},\tau}|^2}{g} - \text{Tr}[\log(\mathbb{G}^{-1})], \quad (6)$$

where

$$\mathbb{G}^{-1} = \begin{pmatrix} -\partial_\tau + \frac{1}{2m} \nabla_{\mathbf{r}}^2 + \mu_\uparrow & \Delta_{\mathbf{r},\tau} \\ \Delta_{\mathbf{r},\tau}^* & -\partial_\tau - \frac{1}{2m} \nabla_{\mathbf{r}}^2 - \mu_\downarrow \end{pmatrix}. \quad (7)$$

The path integral over the pair field $\Delta_{\mathbf{r},\tau}$ cannot be taken analytically, but if one assumes a condensate of pairs is present, then the Bogoliubov shift can be introduced, writing the pair field as

$$\Delta_{\mathbf{r},\tau} = \Delta + \delta_{\mathbf{r},\tau}. \quad (8)$$

Here Δ is the (saddle-point) order parameter of the uniform system, assumed independent of position and imaginary time, and chosen real. It represents a shift of the pair field such that the quantum (and thermal) fluctuations $\delta_{\mathbf{r},\tau}$ can be treated as small. In that case, the Gaussian approximation can be made in which the effective action is expanded up to second order in the fluctuations. Thus, the effective action for the pair field is written as

$$S_{\text{eff}} \approx S_{\text{sp}} + S_{\text{fluct}}, \quad (9)$$

where S_{fluct} is the fluctuation action described in the next section. This fluctuation action contains the information on the Anderson and Higgs modes, and is the main subject of this paper. For completeness, we mention that the saddle point action S_{sp} is given by

$$S_{\text{sp}} = -\frac{\beta V}{q} |\Delta|^2 - \frac{V}{(2\pi)^3} \int d\mathbf{k} \{ \log[2 \cosh(\beta E_k) + 2 \cosh(\beta \zeta)] - \beta \zeta_k \}, \quad (10)$$

with $\zeta_{\mathbf{k}} = k^2/(2m) - \mu$ where $\mu = (\mu_\uparrow + \mu_\downarrow)/2$, $\zeta = (\mu_\uparrow - \mu_\downarrow)/2$, and V is the volume. The Bogoliubov energy related to breaking up a pair is given by

$$E_{\mathbf{k}} = \sqrt{\zeta_{\mathbf{k}}^2 + |\Delta|^2}. \quad (11)$$

Note that the precise value of the saddle point is obtained from the gap equation $\partial S_{\text{sp}}/\partial \Delta = 0$, which corresponds to minimizing the action for the pair field. This equation should be solved in conjunction with the number equation, fixing the density $n = -\partial \Omega/\partial \mu$ where Ω is the thermodynamic potential. However, the question of the value of the saddle point and the equation of state is separate from the study of the fluctuations. As we discuss below, the fluctuation propagator depends only on the ratio μ/Δ (and the temperature). This means that one can use an equation of state of one's own choice to relate this quantity to the density and the interaction strength: the mean-field equation of state, the experimentally determined one, or the one from Monte Carlo simulations. This is an often overlooked but important aspect of the study of small-amplitude fluctuations in fermi superfluids.

Gaussian fluctuations of the pair field

Having introduced the order parameter Δ in the previous section, we now turn to the question of small amplitude variations of this field. Since we are interested in phase (Anderson–Bogoliubov) and amplitude (Higgs) modes, it is convenient to write the fluctuations also in amplitude and phase representation:

$$\Delta_{r,\tau} = (\Delta + a_{r,\tau}) \exp\{i\theta_{r,\tau}\}. \quad (12)$$

The fluctuation action is best expressed not in real space but in reciprocal space coordinates, namely, the center-of-mass wave-number $\mathbf{q}$ of the pair and the bosonic Matsubara frequencies $\omega_n = 2\pi n/\beta$. In terms of the reciprocal space fluctuation fields $a_{\mathbf{q},n}$ and $\theta_{\mathbf{q},n}$, the fluctuation action in Nambu notation is given by

$$S_{\text{fluct}} = \frac{1}{\beta V} \sum_{\mathbf{q},n} (\theta_{\mathbf{q},n} \quad \Delta a_{\mathbf{q},n}) \cdot \begin{pmatrix} M_{++} & -iM_{+-} \\ iM_{-+} & M_{--} \end{pmatrix} \cdot \begin{pmatrix} \theta_{\mathbf{q},n}\Delta \\ a_{\mathbf{q},n} \end{pmatrix}. \quad (13)$$

The “fluctuation” matrix in (13) will be denoted by $\mathbb{M}(\mathbf{q}, i\omega_n)$. The inverse fluctuation matrix $\mathbb{M}^{-1}(\mathbf{q}, i\omega_n)$ is interpreted as the propagator for the (coupled) amplitude and phase modes, and as such it takes center stage in our study of these modes. The dispersion and the lifetime of the coupled phase (Anderson–Bogoliubov) and amplitude (Higgs) modes are found via the real and imaginary poles of the propagator $\mathbb{M}^{-1}(\mathbf{q}, i\omega_n)$, analytically continued to the complex plane ($i\omega_n \rightarrow z$), or equivalently, via the roots of $\det(\mathbb{M})$. Its matrix elements are given by

$$\begin{aligned} M_{\pm\pm}(\mathbf{q}, z) = & \sum_{\mathbf{k}} \frac{X(E_+) + X(E_-)}{8E_+E_-} (E_+E_- + \xi_+\xi_- \pm \Delta^2) \left(\frac{1}{z - (E_+ + E_-)} - \frac{1}{z + (E_+ + E_-)} \right) \\ & + \sum_{\mathbf{k}} \frac{X(E_+) - X(E_-)}{8E_+E_-} (E_+E_- - \xi_+\xi_- \pm \Delta^2) \left(\frac{1}{z - (E_+ - E_-)} - \frac{1}{z + (E_+ - E_-)} \right) + \sum_{\mathbf{k}} \frac{X(E_{\mathbf{k}})}{2E_{\mathbf{k}}}, \end{aligned} \quad (14)$$

and

$$\begin{aligned} M_{+-}(\mathbf{q}, z) = & \sum_{\mathbf{k}} \frac{X(E_+) + X(E_-)}{8E_+E_-} (E_- \xi_+ + E_+ \xi_-) \left(\frac{1}{z - (E_+ + E_-)} + \frac{1}{z + (E_+ + E_-)} \right) \\ & + \sum_{\mathbf{k}} \frac{X(E_+) - X(E_-)}{8E_+E_-} (E_- \xi_+ - E_+ \xi_-) \left(\frac{1}{z - (E_+ - E_-)} + \frac{1}{z + (E_+ - E_-)} \right), \end{aligned} \quad (15)$$

where we used shorthand notations $E_{\pm} = E_{\mathbf{k} \pm \mathbf{q}/2}$ and $\xi_{\pm} = \xi_{\mathbf{k} \pm \mathbf{q}/2}$ and introduced the function

$$X(E) = \frac{\sinh(\beta E)}{\cosh(\beta E) + \cosh(\beta \zeta)}. \quad (16)$$

These matrix elements, discussed here in the context of the path-integral description, can equally be found in the Gaussian random-phase approximation. In the form given above, the matrix elements have units of inverse energy, and when multiplied by $1/\beta$ in expression (13), the result becomes dimensionless, and will depend only on the ratio μ/Δ and on the reduced temperature $\beta\Delta$. This means that the result is expressed in a form independent of the chosen equation of state that is used to relate the system parameters a_s and k_F to μ/Δ and $\beta\Delta$.

Care must be taken with the analytic continuation for values of z in the lower half complex plane $\text{Im}(z) < 0$. Both formalisms yield the propagator as a thermal Green’s function, defined for the bosonic Matsubara frequencies $i\omega_n$. Experiments measure response functions, given in Kubo’s formalism by the retarded Green’s functions obtained by replacing $i\omega_n \rightarrow \omega + i\varepsilon$ with ε an infinitesimal. When we search for quasiparticles (Anderson–Bogoliubov phonons or Higgs particles) in the superfluid, we need to look for poles in the lower half complex plane. However, the real axis itself is a branch cut since the integrations over the wave numbers $\mathbf{k}$ yield integrals of the form

$$F(z) = \int_{-\infty}^{+\infty} \frac{f(v)}{z - v} dv. \quad (17)$$

At temperature zero, this cut starts from $\min_{\mathbf{k}}(E_+ + E_-) = 2\Delta$, and at nonzero temperature, the entire real line is a branch cut. To cross this branch cut, one must follow Nozières’ prescription

$$\text{Im}(z) < 0 \rightarrow F(z) = \int_{-\infty}^{+\infty} \frac{f(v)}{z - v} dv + 2\pi i f(z). \quad (18)$$

This brings another difficulty: the function in the numerator $f(v)$ must itself be analytically continued into the lower half plane. For the integrals in (14) and (15), the functions in the numerator are piecewise analytic as they contain kinks at energies where new channels for decay open up. Hence one must choose the window through which the analytic continuation is performed. The natural choice for this is to choose the window in which $v = \Re(z)$ is contained. The switching of windows as $\Re(z)$ is varied leads to kinks or discontinuities in the dispersion and lifetimes of the Anderson and Higgs modes, which can be interpreted as physically resulting from additional decay modes becoming available.

Before looking in more detail at the collective modes calculated from this theory, it is useful to start with a schematic overview of the commonly agreed qualitative results (at low temperature), as shown in Fig. 1. The collective mode spectrum is influenced by the presence of a continuum of single-particle (pair-breaking) excitations, shown as a shaded region. This influence becomes negligible

Fig. 1 Schematic overview of the collective modes in the BEC–BCS crossover of a fermionic superfluid at low temperature. The pair-breaking continuum is shown as a shaded region. The Anderson–Bogoliubov mode (full red curve) starts as a sound mode at low momentum. The Higgs mode is only present in the BCS regime and is indicated by a dashed red curve.

in the BEC limit, as the pair breaking continuum shifts to higher and thermally inaccessible energies. In the BEC limit, the Anderson–Bogoliubov mode (shown as a full red curve) corresponds to the Bogoliubov spectrum of Eq. (2) for a gas of point bosons (the tightly bound pairs). The spectrum starts linear, and curves up at higher momenta. There is no Higgs (amplitude) mode present in the BEC case, as discussed in section “Collective modes in Bose condensates.” However, as one shifts to the BCS side of the crossover, the pair breaking continuum comes down in energy as the sound velocity increases. The Anderson–Bogoliubov mode is repelled by the continuum and the curvature turns from positive to negative. In addition, the amplitude mode (dashed red curve) appears close to the pair breaking gap 2Δ , and disperses upward while also acquiring a larger damping, washing out this mode at larger momenta. In the next sections, we will go into detail about the Anderson–Bogoliubov mode and the amplitude mode, and sketch how the above picture originated from the various theoretical and experimental investigations.

Anderson–Bogoliubov mode in superfluid Fermi gases

The poles of the propagator are found by solving $\det[\mathbb{M}(\mathbf{q}, z)] = 0$ with respect to z for any given wave number $\mathbf{q}$. These poles reveal the collective modes of the Fermi superfluid, as already noted by Sa de Melo et al. (1993). However, it was only recently that this equation was solved in its entire complexity. Initial studies focused on simplifications (ignoring the coupling between amplitude and phase modes, ignoring damping) and limiting cases (long wavelength and temperature zero). Below, we take the reader more or less chronologically through the various steps taken in the study of the Anderson–Bogoliubov mode in the Fermi superfluid gas.

The Anderson–Bogoliubov mode at long wavelength $q \rightarrow 0$ has a sound-like dispersion $\omega = cq$, and initially the sound velocity was obtained at zero temperature (Sa de Melo et al., 1993; Marini et al., 1998; Huang and Wan, 2007; Diener et al., 2008) by expanding the matrix elements of $\mathbb{M}(q, \omega)$ for small q and small ω . However, this expansion turns out to be problematic as the point $(q, \omega) = (0, 0)$ is a branch point for the matrix (at any temperature) such that the limiting value depends on the path followed in the q, ω plane. Therefore, there is no Taylor expansion valid everywhere in the vicinity of the $(q, \omega) = (0, 0)$ point.

Other initial investigations, such as Ohashi and Griffin (2003) focused on solving $M_{++} = 0$ and thus neglecting the coupling between the phase and amplitude modes. In the BCS limit, $\mu/\Delta \rightarrow \infty$ as the gap approaches zero exponentially. In that case, M_{+-} approaches zero, and the phase and amplitude sectors decouple so that the phase mode is indeed solved by $M_{++} = 0$. However, for a general coupling strength in the BEC–BCS crossover, this is no longer the case, and the mixing of phase and amplitude modes must be taken into account.

The full dispersion at temperature zero was obtained by Combescot et al. (2006), which matches results obtained by the random phase approximation (Kurkjian et al., 2016). These results are in the collisionless regime, but they agree reasonably well with the results obtained in the hydrodynamic regime (Heiselberg, 2006; He et al., 2007) via the relation $c = (n/m)\partial\mu/\partial n$, which however requires a choice of equation of state, for which Astrakharchik et al. (2005) used the Monte Carlo equation of state.

The Anderson–Bogoliubov mode has a finite lifetime, even at zero temperature. Sophisticated low-energy effective theories were developed to go beyond hydrodynamics and capture the first dispersive correction to the spectrum (Salasnich and Toigo, 2008; Mañes and Valle, 2009; Rupak and Schäfer, 2009). The finite lifetime of the phonons at $T = 0$ was obtained by considering Beliaev processes (Kurkjian et al., 2017). In these results the lifetime is calculated in a perturbative way, by including the decay processes diagrammatically, for example. However, a nonperturbative result can be found by locating the zeroes of $\det[\mathbb{M}(\mathbf{q}, z)]$ numerically in the lower complex z plane, using the analytic continuation (18), as shown by Klimin et al. (2019a,b). This work also addressed the temperature dependence of the mode’s dispersion and damping.

In contrast with the low-temperature regime, the behavior of the collective branches near T_c long remained a controversial problem. Whereas Andrianov and Popov (1976) find a purely imaginary dispersion, Ohashi and Takada (1997) find a real dispersion. Both studies were performed in the BCS limit $\mu/\Delta \rightarrow \infty$, whereas a more recent study is limited to the strong-coupling regime (Kosztin et al., 2000). The controversy was solved in Klimin et al. (2019b), where it is shown that in the vicinity of the

transition temperature T_c a second sound-like mode appears, corresponding to a second solution of $\det[\mathbb{M}(\mathbf{q}, cq)] = 0$. The second mode is not present in the BEC regime. The two-mode nature is also visible in the order-parameter phase response function which displays two distinct resonance peaks, at temperatures relatively close to T_c , and in the BCS regime. The second mode, obtained in the random phase approximation as well as in the Gaussian pair fluctuation approach outlined in the previous sections, has a counterpart in superconductors, where it is known as the Carlson–Goldman mode, observed experimentally by Carlson and Goldman (1973, 1976). There, the Anderson–Bogoliubov mode is no longer sound-like due to the charged nature of the pairs, but the second mode, existing only close to T_c , remains sound-like.

Let us now turn to experiments in ultracold Fermi gases. As discussed in the section “Order parameter for the superfluid Fermi gas,” Feshbach resonances allowed to boost the critical temperature for pair formation and superfluidity to within experimental reach. The sound velocity in these systems was first observed by creating a density perturbation and observing its displacement grow linearly with time (Joseph et al., 2007; Sidorenkov et al., 2013; Weimer et al., 2015). In the BEC regime the sound velocity determines the Landau critical velocity for superfluid flow (whereas in the BCS regime, the pair-breaking excitations do), and this provides an indirect way to determine the velocity of the sound mode on the BEC side of unitarity (Miller et al., 2007).

The complete excitation spectrum (i.e., beyond the long-wavelength limit given by the sound velocity) was measured in a seminal experiment by (Hoinka et al., 2017), using Bragg spectroscopy. When the imparted momentum and energy are resonant to an elementary excitation (such as an Anderson–Bogoliubov excitation), a peak in the number of Bragg scattered atom number is detected. Strongly speaking, the Bragg probe couples to the atom density rather than to the pair phase, but the two are coupled such that the Anderson–Bogoliubov mode can be both excited and probed by this technique.

A comparison between the experimentally measured Anderson–Bogoliubov response and the Gaussian pair fluctuation theory (Klimin et al., 2019b) is shown in Fig. 2. Theory and experiment are seen to be in fair agreement. Nevertheless, many questions remain, such as how to improve qualitative results of the curvature of the Anderson–Bogoliubov mode as a function of the interaction strength. The precise value of the interaction strength where the curvature switches from positive to negative is very

Fig. 2 Comparison between theory and experiment for the Anderson–Bogoliubov mode. The symbols correspond to Bragg spectroscopy measurements (Hoinka et al., 2017), the full line is the result from Gaussian pair fluctuation theory (Klimin et al., 2019b). The measurements were performed at finite wave number $k \approx k_F/2$ (panel A), from which the long-wavelength $k \rightarrow 0$ data was extrapolated (panel B). Anderson–Bogoliubov collective excitations in superfluid Fermi gases at nonzero temperatures. *Journal of Low Temperature Physics* 196: 102–110.

Fig. 3 (A) In the experiment of Patel et al. (2020), a density wave is excited by shaking one of the walls of a box trap containing a Fermi superfluid near unitarity. The damping of the wave away from the wall is visible. (B) The measured resonant frequency (dots) corresponds to that of the Anderson–Bogoliubov mode (full line) since near unitarity there is a good coupling between the phase mode of the order parameter and the density oscillation. Reproduced with permission from Patel PB, Yan Z, Mukherjee B, Fletcher RJ, Struck J, Zwierlein MW (2020). Universal sound diffusion in a strongly interacting Fermi gas. *Science* 370: 1222–1226.

sensitive to the microscopic theory for the pairing and can be seen as test for it. Experimentally, the Carlson–Goldman mode near the critical temperature, and, in general, the temperature dependence remain to be measured.

The damping of the Anderson–Bogoliubov mode has only recently been observed directly, although it possibly could be extracted from the width of the Bragg excitation peaks in Hoinka et al. (2017). A recent experiment by Patel et al. (2020) takes a more direct approach; its results are shown in Fig. 3. In this experiment, the Fermi superfluid is enclosed in a box trap in which one of the walls of the box is shaken to excite the sound mode. The damping of the amplitude of the mode away from the wall can then be related to the sound attenuation in the Fermi superfluid (Braby et al., 2010). A difficulty that remains is that the shaking excites a density wave, which is strictly speaking different from the phase mode—however, both are coupled in such a way that at the resonant frequency, the phase mode is visible in the density response.

Amplitude mode in superfluid Fermi gases

The first theoretical efforts to describe the amplitude mode were performed in the context of superconductors. There, the Coulomb interactions between the charged pairs create a gap for the phase mode, lifting it to a plasmonic start. However, the amplitude mode is expected to remain present near 2Δ . Initial studies (Schmid, 1968; Kulik et al., 1981; Littlewood and Varma, 1981, 1982) assumed particle–hole symmetry, which is only valid in the BCS limit, as well as the long-wavelength limit $q \rightarrow 0$. This corresponds to solving $M_{-}(\mathbf{q} \rightarrow 0, z) = 0$, rather than $\det[M(\mathbf{q}, z)] = 0$. As mentioned in the introduction, this approximation is not valid for superfluid Fermi gases.

Liu et al. (2016) studied the amplitude mode through the Ginzburg–Landau equation for the superfluid Fermi gas. This can be obtained by a gradient expansion of the action, valid for slow frequencies and long wavelength. However, it is not clear whether this approach is valid at frequencies comparable to $2\Delta/\hbar$. The result of $\det[M(\mathbf{q}, z)] = 0$ at arbitrary wave number was first studied in Kurkjian et al. (2019), obtaining the full dispersion relation of the amplitude mode, accounting for amplitude–phase coupling. This includes a calculation of the damping rate, which is shown to have a quadratic start at low wave number rather than the previously assumed linear one (Littlewood and Varma, 1982). The amplitude mode is shown to appear in the BCS regime at $\mu/\Delta \simeq 0.8267$. At zero temperature, analytical results for the dispersion were obtained in Kurkjian and Castin (2020). Analysis of the fluctuation matrix at nonzero temperature reveals that when approaching the critical temperature from below, the Anderson–Bogoliubov mode persists only in a relatively low energy-momentum region, and is gradually replaced by a quadratically dispersed pairing resonance (Klimin et al., 2021). This also leads to a decrease in the Landau critical velocity, which tends to zero as the temperature tends to the critical temperature. The general conclusion for the amplitude mode is that it persists well into the crossover regime of strongly correlated fermionic superfluids, and is not overdamped so that it should be experimentally detectable. Fig. 4 (reproduced from Kurkjian et al., 2019) shows the response function of the superfluid in the pair-breaking continuum, and in the BCS regime at $\mu/\Delta = 10$. The Higgs mode is clearly visible at low momentum, and the long-wavelength analytic results for the dispersion match the peak of response function well, even as it becomes more strongly damped.

However, in contrast to the Anderson–Bogoliubov mode, the amplitude mode is much harder to detect in practice. The presence of the broken-pair continuum dampens the mode, and it is not a priori clear how to disentangle the signal of the amplitude mode from the response of the pair-breaking excitations (Cea et al., 2016). The amplitude mode is also much harder to excite: many “pump” protocols (such as Bragg scattering) use fields that couple to the density rather than to the amplitude of the order parameter. Whereas the phase sector couples well to the density, a question remained as to how strongly the amplitude of the order parameter couples to it. Following a suggestion made by Volkov and Kogan (1974) for superconductors, Scott et al. (2012) therefore propose to modulate the scattering length via a Feshbach resonance as a way to excite the (long-wavelength) amplitude mode directly. This

Fig. 4 The pair-field response function of the Fermi superfluid is shown in the pair-breaking continuum region ($\omega > 2\Delta$). Despite the presence of strong damping at larger wave numbers, the amplitude mode is clearly visible at lower momenta. The analytic dispersion (*full red line*) matches with the maximum of the broadening peak (*dashed line*) in the numerically computed response. The *white dashed line* is the quadratic long-wavelength limit. Reproduced with permission from Kurkjian H, Klimin SN, Tempere J, Castin Y (2019). Pair-breaking collective branch in BCS superconductors and superfluid Fermi gases. *Physical Review Letters* 122: 093403.

proposal was investigated theoretically in the framework of the Bogoliubov–de Gennes approach (but still in the long-wavelength limit) by Tokimoto et al. (2017). Kurkjian et al. (2020) studied the linear response functions where both the pump and the probe can couple to amplitude, phase, or density and showed that an experiment where the pump couples to the amplitude of the order parameter (such as the “wiggling” of the scattering length) will provide a measurable signal of the amplitude mode in the density channel. Crucially, Kurkjian et al. (2020) also showed that the amplitude mode is detectable not only in the amplitude–amplitude and amplitude–density response functions but also in the density–density responses.

Behrle et al. (2018) developed a scheme for exciting the amplitude mode that does not rely on modulating the scattering length. Rather, they induce a radio-frequent coupling between one of the pairing states, denoted by $|2\rangle$ and an unoccupied hyperfine spin state, $|3\rangle$. This modulates the pairing between the two states $|1\rangle$ and $|2\rangle$ that form the superfluid. After the excitation, the condensate fraction is measured by a quick sweep to the BEC regime, projecting onto tightly bound pairs. Thus, the detection is also more closely linked to the amplitude channel than to the density channel. Behrle et al. (2018) detect a resonance at the modulation frequency 2Δ that is attributed to the amplitude mode, and that broadens when the system is tuned to the BEC side. To this date, this remains the only observation of the amplitude mode in superfluid Fermi gases, although a full theoretical analysis of the particular experimental procedure is still lacking. Other researchers follow more closely the proposal of modulating the interaction strength. In particular, Dyke et al. (2021) mapped the response of the order parameter to a quench in the interaction strength. This reveals the formation of the pairs, but the long-wavelength response is much slower. Supposedly, extending this experiment from a quench to a periodical modulation will allow to reveal the amplitude mode. However, at the time of writing, this measurement remains to be performed.

Conclusion

It is clear that the advent of superfluid Bose and Fermi gases offer a new and versatile approach to studying the phase and amplitude mode that follow from breaking $U(1)$ symmetry. These modes were originally defined and studied in the context of particle physics and superconductors, but the atomic gases offer a much cleaner system, where interaction strength, dimensionality, and composition can be finely tuned experimentally. This has allowed to extend earlier studies to now encompass damping, nonzero wave number, and temperature effects of these modes. At the same time, differences have been revealed with superconducting systems, due to the charge neutrality of the superfluid gases. Despite these advances, challenges remain to excite and probe these modes experimentally, for which the coupling between the modes and the coupling with the suitable experimental probes should be better understood, perhaps even beyond the linear regime.

Abstract

Optical and acoustic phonons play a central role in solid-state physics. Acoustic phonons can be thought of either as Goldstone bosons, which arise from the breaking of the translational invariance, or as gauge bosons within a non-Abelian gauge theory framework. Nevertheless, optical phonons are left out. Spontaneous symmetry breaking provides a unified framework in which optical and acoustic phonons appear together. After a general overview of this subject, the concept was applied specifically to crystalline phase transitions. Goldstone and Higgs modes arise naturally as a result of spontaneous breaking of a global, continuous crystal symmetry and can be identified with acoustic and optical phonons, respectively.

Key points

- The emergence of Goldstone modes in crystals, ensuing from the spontaneous breakdown of the translational invariance due to the lattice.
- Solid crystal lattice, phonons, and sonic metric: similarities with the general relativity formalism.
- By requiring Lagrangian gauge invariance, the acoustic phonons appear as gauge bosons. They are self-interacting due to the noncommutative Lie algebra of group generators.
- Introduction to the Spontaneous Symmetry Breaking: the emergence of order parameters and Higgs modes.
- Optical and acoustic phonons in crystals are Higgs and Goldstone lattice excitations caused by the spontaneous breaking of a global, continuous symmetry.
- Phase transitions in metals and experimental evidences of spontaneous symmetry breaking.

Introduction

When a continuous symmetry breaks, a massless bosonic particle appears for each broken generator. This is the short version of the Nambu–Goldstone theorem (Nambu, 1960; Goldstone, 1961), which forms the basis of the Standard Model of fundamental interactions. However, the Goldstone theorem is very general and is valid also in the nonrelativistic condensed matter, where the massless bosons correspond to collective excitations with wavevector $\mathbf{k}$ and gapless frequency dispersion relation $\omega_{\mathbf{k}}$, that is, $\omega_{\mathbf{k} \rightarrow 0} \rightarrow 0$, where $k = |\mathbf{k}|$. Some examples: Spin waves in the Heisenberg model are bosons that appear when the ground state of the

Heisenberg–Hamiltonian is magnetically ordered (Kendziora et al., 2005); collective density excitations in superconductors arise from spontaneous breaking of the electronic phase rotation symmetry $U(1)$ (Pracht, 2017; Pracht et al., 2017). A more known example is given by acoustic phonons (Ashcroft and Mermin, 1976), collective excitations in crystalline solids associated with lattice vibrational modes. They correspond to Goldstone modes arising from the breaking of a continuous spatial symmetry, the translational invariance, which is broken by the presence of the crystal lattice (Leutwyler, 1994, 1997). All of these collective excitations are said to arise from one of the so-called emergence principles, in this case the Goldstone theorem, since they arise from the beginning.

The nature of acoustic phonons can be reinterpreted in the context of a non-Abelian gauge theory in which translations play the role of the gauge group. Following a formalism very similar to the Yang–Mills theory of the affine group, the local gauge invariance imposed on the Lagrangian leads to gauge fields identified with acoustic phonon modes (Vallone, 2019).

An important topic in physics is spontaneous symmetry breaking (SSB): it is widely known in the Standard Model of particle physics, where the mass-generating mechanism described by Higgs (1964) removed the obstacles encountered in the attempt to construct a unified gauge invariant theory of the electromagnetic and weak interactions (Mandl and Shaw, 2010). In condensed matter physics a similar concept was formulated by Ginzburg and Landau (Ginzburg and Landau, 1950; Landau, 1965), an approach that inspired Anderson (1963) to describe the plasmon phenomenon in a way that was recognized by Higgs himself as cornerstone for his own work. The existence of such oscillating modes seems to be ubiquitous. The Higgs mechanism has been recognized in topological insulators, Weyl semimetals, and in cuprates (Hasan and Kane, 2010; Ando, 2013; Wan et al., 2011; Burkov and Balents, 2011; Singh et al., 2012; Raines et al., 2015); in the quantum phase transition between superfluid and insulating phases (Littlewood and Varma, 1981; Endres et al., 2012); in the transition from a sea of spin-singlet pairs to a long-range antiferromagnet (Rüegg et al., 2008); in superconductors (Pracht, 2017; Pracht et al., 2017), etc. Recently, the presence of structural Goldstone and Higgs modes was suggested by first-principles calculations (Marthinsen et al., 2018) on a perovskite oxide, SrMnO_3 , and demonstrated in a supersolid quantum gas (Léonard et al., 2017).

It has been shown that even the well-known optical and acoustic phonons in crystalline solids (metals, semiconductors, etc.) can be identified, respectively, with Higgs and Goldstone excitations of the crystal lattice which arise from the spontaneous breaking of a global, continuous symmetry in structural phase transitions that occur in widely available, natural crystalline solids (Vallone, 2019; Meier et al., 2019; Juraschek et al., 2020; Vallone, 2020). This important fact complements similar occurrences in quantum phase transitions and shows how widespread such concepts are in seemingly unrelated branches of physics.

Overview and outline of the chapter

In order to depict what will be covered in the sections that follow, it is important to note that the current chapter includes a number of concepts and themes that are strictly related to one another.

Section “Symmetry and invariance” provides an overview of the concepts of symmetry of states, symmetry of Hamiltonian (or action), and invariance, which are required to address what follows, particularly the concept of spontaneous symmetry breaking.

In Section “Gauging translations in crystal lattice: Acoustic phonons as gauge bosons,” after a description of the acoustic phonons as Goldstone bosons arising from the breaking of the translational invariance, we introduce a different concept: the gauging of spatial translations on the lattice. This reinterprets the acoustic phonons in the framework of a non-Abelian gauge theory, in which translations play the role of the gauge group. From this point of view, the nonlinearity of phonon–phonon interactions arises naturally from the noncommutative Lie algebra of the group generators involved. However, this approach does not describe another, even more important oscillatory mode of the crystal lattice: optical phonons.

In Section “Spontaneous symmetry breaking and order parameter” we first discuss the general concept of SSB. Then we show how acoustic and optical phonons in crystals can be described as Goldstone and Higgs modes emerging from an SSB caused by a transition from a symmetric crystalline phase to a less symmetric phase. Considering the great importance of optical phonons for electronic transport in semiconductors (Brum and Bastard, 1986; Vallone et al., 2015, 2017), this topic is particularly important. We also emphasize that nonlinear multiphonon coupling, phonon decay, and the acousto-optical coupling are all described by this unifying approach, and they are the result of the Lagrangian nonlinearities (Vallone, 2020; Xie, 2022).

Notation

In the present work A^α and B_β are contravariant and covariant four-vectors, ∂_μ is the partial derivative $\partial/\partial x^\mu$, where Greek indices $\alpha, \beta, \mu, \dots = 0, \dots, 3$ mark space–time coordinates on a four-dimensional differentiable manifold with metric $g_{\mu\nu}$ and connection $\Gamma^\alpha_{\mu\nu}$. Latin indices $(i, j, k, \dots = 1, 2, 3)$ indicate spatial components, while Greek indices with a ‘hat’ $\hat{\mu}, \hat{\nu}, \dots = 0, \dots, 3$ are used for indices of local four-dimensional frames (vierbeins or tetrad indices) on a flat Lorentzian space–time with Minkowski metric $\eta_{\hat{\mu}\hat{\nu}} = \text{diag}(+1, -1, -1, -1)$. Einstein summation over the repeated index is always understood, the nonitalicized ‘i’ is the imaginary unit, square brackets $[A, B]$ represent the commutator $AB - BA$, the operator $\hat{U}^\dagger$ is the Hermitian conjugate of $\hat{U}$, and ψ^* is the complex conjugate of ψ .

Symmetry and invariance

Until the 20th century, the principles of symmetry played little role in theoretical physics. This changed dramatically with A. Einstein, whose breakthrough in 1905 was to put symmetry first and to regard the principle of symmetry as the primary feature of nature that restricts dynamical laws to an admissible path. From this new perspective, the transformation properties of the electromagnetic field do not derive from Maxwell's equations, but rather are a consequence of relativistic invariance, from which the form of Maxwell's equations follows.

With the development of quantum mechanics in the 1920s, symmetry principles were elevated to an even more fundamental role, which is now the predominant concept in the study of the properties of matter and the universe at the deepest level and serves as the guiding principle in the search for the grand unification laws.

To get to our topic and discuss what a spontaneous symmetry breaking is, we must first briefly recall what a symmetry is. To this end, we must distinguish the symmetry of physical states, objects, and solutions of equations of motion from the symmetry of the laws that govern them, which is a different concept.

Symmetry of states

When an object appears identical from different angles, we say that it is symmetrical. For example, if it is rotated through any angle, it may appear identical. A sphere is a classic case, and we say that it has continuous rotational symmetry: its shape is invariant by rotations. A book, a cat, a man, etc. have no rotational symmetry. A cylinder has cylindrical symmetry, that is, it looks the same—it is invariant—when rotated about its longitudinal axis (but this is not true for rotation about any other axis). These are continuous symmetries, but there are also discrete symmetries. One example is spatial parity, which is defined by a change in the sign of all spatial coordinates. A reflection symmetry is the flipping of one spatial coordinate (e.g., $x, y, z, \rightarrow -x, y, z$): we have roughly reflection symmetry since our shape is approximately invariant when mirrored. However, in this paper, we will only consider continuous symmetries.

Although the concept of symmetry and the related conservation laws can be presented in a classical context, they can be discussed in quantum mechanics in a much simpler yet general form. A state $|\psi\rangle$ is said to be symmetric under a transformation U (e.g., represented as a matrix) if the transformed state is the same initial state except for a phase factor, that is, $U|\psi\rangle = e^{i\phi}|\psi\rangle$, where ϕ is a real parameter. Since a phase factor does not correspond to any observable, the new state has the same properties as the initial state, including the same norm. The last point implies that the associated operator $\hat{U}$ is unitary.

The unitary transformations form a group, and $\hat{U}$ can be given the exponential form $\hat{U} = e^{i\phi^i \hat{P}_i}$, where ϕ^i are real parameters and $\hat{P}_i$ are called the generators of the group ($i = 1, 2, 3$, in the ordinary space). Continuous spatial translations in the ordinary space have three generators (the momentum operator components) that fulfill the Lie algebra $[\hat{P}_j, \hat{P}_k] = i f_{jk}^i \hat{P}_i$, where f_{jk}^i are called structure constants of the algebra (Ziman, 1969; Peskin and Schroeder, 1995; Lipkin, 2002).

An important note: The transformed state is not the same as the initial state, but it seems that the difference is not observable. However, this is not the case: if $\hat{U}$ is applied to another state $|\chi\rangle$ and the transformed state cannot be expressed by $e^{i\phi}|\chi\rangle$, we say that $|\chi\rangle$ is not symmetric with respect to the group of transformations represented by $\hat{U}$. From the comparison we conclude that $|\psi\rangle$ is symmetric and $|\chi\rangle$ is not, while without the comparison we could conclude that $\hat{U}$ is the identity operator, which is not true.

Symmetry of the physical laws

The second point we need to discuss is the symmetry of the physical laws governing quantum states: in particular, the symmetry of the equations of motion (e.g., the Euler–Lagrange or Schrödinger equations), which derive their symmetry properties from the symmetry of Hamiltonians, Lagrangians, or action.

A system is called symmetric if it is described by a Hamiltonian operator $\hat{H}$ (or by a Lagrangian operator $\hat{\mathcal{L}}$), which is invariant under a unitary transformation $\hat{U}$ which commutes with the Hamiltonian operator, $[\hat{U}, \hat{H}] = 0$, or equivalently $\hat{U}^\dagger \hat{H} \hat{U} = \hat{H}$. The reason is the following: It is easy to prove that the energy E_n associated to an eigenstate $|\psi_n\rangle$ of $\hat{H}$ does not change if we transform the state to $\hat{U}|\psi_n\rangle$ provided $[\hat{U}, \hat{H}] = 0$, even if $|\psi_n\rangle$ itself is not symmetric under the transformation $\hat{U}$:

$$\hat{H}(\hat{U}|\psi_n\rangle) = \hat{U}(\hat{H}|\psi_n\rangle) = E_n(\hat{U}|\psi_n\rangle). \quad (1)$$

In Eq. (1), we have only exploited the commutation rule $[\hat{U}, \hat{H}] = 0$, but no symmetry constraints have been set for the state $|\psi_n\rangle$. More formally, $\hat{H}$ and $\hat{U}^\dagger \hat{H} \hat{U}$ represent the same dynamics: if $\hat{U}$ commutes with the Hamiltonian, the eigenstates of $\hat{H}$ are also eigenstates of the transformed Hamiltonian $\hat{U}^\dagger \hat{H} \hat{U}$ with the same eigenvalues. We say that the transformation represented by $\hat{U}$ is a symmetry of the Hamiltonian.

All this is closely related to conservation laws. The relationship between symmetries and conserved quantities can be understood by noting that the Hamiltonian operator defines the time evolution unitary operator $\hat{T} = e^{i\hat{H}t}$, for which $[\hat{T}, \hat{H}] = 0$ holds. $\hat{T}$ can also be written in the exponential form $\hat{T} = e^{i\hat{Q}}$, and since $[\hat{Q}, \hat{T}] = 0$ also holds, the expectation value of $\hat{Q}$ in any state $|\psi\rangle$ is conserved in time (Heisenberg equation): its eigenvalue is a conserved quantity, a constant of motion.

All this has an important consequence: the existence of a symmetry transformation implies a conservation law. For example, symmetry with respect to translations implies conservation of momentum, and symmetry with respect to rotations implies

conservation of angular momentum. Moreover, for continuous symmetry transformations parameterized by a continuous variable, there is an even stronger result, the Noether theorem: a continuous symmetry always implies a current $j^\nu(r, t)$ for which a local conservation law holds: $\partial_\nu j^\nu(r, t) = 0$. There are many more details behind this, but they are far beyond the scope of the present work. The interested reader can find much further food for thought in Gross (1996), and Beekman et al. (2019), beside a demonstration of the Noether theorem in Peskin and Schroeder (1995).

What is still important here is the fact that the local form of the Noether theorem $\partial_\nu j^\nu(r, t) = 0$ only depends on the symmetry of the action with respect to $\tilde{U}$ and is also valid for a stable state which does not have the same symmetry. In the latter case we say that the symmetry of the action is spontaneously broken, a concept that will be presented in detail in Section “Spontaneous symmetry breaking and order parameter.”

Gauging translations in crystal lattice: Acoustic phonons as gauge bosons

The dynamics of nonrelativistic Pauli electrons in crystal lattice (e.g., in a semiconductor, in a metal) with effective mass m_e , wavefunction $\psi_k(t, r)$, and wavevector k can be described by the Lagrangian density

$$\mathcal{L} = i\psi_k^* \partial_t \psi_k - \frac{1}{2m_e} \nabla \psi_k^* \cdot \nabla \psi_k, \quad (2)$$

which is symmetric (i.e., invariant) under global, continuous transformations described by the Galilei group G (Sternberg, 1994; Gilmore, 2008). If H is the group of time translations, the generators of the quotient group G/H are the momentum p (spatial translations), the angular momentum J (rotations), and the boosts K . The spatial translations form the subgroup $T(3)$ in the ordinary space, and the elements of its infinitesimal form are the operators $U_T = 1 - ik \cdot \delta R$, where δR is an infinitesimal displacement of the crystal ions in space around a Bravais lattice translation vector R (Ashcroft and Mermin, 1976). U_T may be written as $U_T = 1 - \varepsilon^j p_j$, where ε_j are real parameters, and the momentum components $p_j = -i\hbar \partial_j$ are the three generators of $T(3)$, which obey the Lie algebra $[p_i, p_j] = 0$. Similar considerations could be made for the other two subgroups.

Emerging of Goldstone modes

The underlying crystal lattice can be described (Peskin and Schroeder, 1995) as a periodic potential $V(\phi)$ to be inserted into a Lagrangian given by $\mathcal{L} = \text{kinetic term} - V(\phi)$. The fields ϕ^j transform under the action of U_T as $\phi^j \rightarrow \phi^j + \alpha(\phi)p^j$, where $\alpha(\phi)$ is an infinitesimal parameter. As a consequence, the lattice breaks both translational and rotational invariances, making the system ground state not symmetric. On the other hand, the Lagrangian symmetry may remain exact, provided

$$V(\phi^j) = V(\phi^j + \alpha(\phi)p^j). \quad (3)$$

Taylor expanding the Eq. (3), the same condition can be written as

$$\alpha(\phi) \frac{\partial V(\phi)}{\partial \phi^j} = 0, \quad (4)$$

and differentiating the Eq. (4) with respect to ϕ^k around a potential minimum ϕ_0 (corresponding to one of the ions equilibrium positions), we obtain

$$\left(\frac{\partial \alpha(\phi)}{\partial \phi^k} \frac{\partial V}{\partial \phi^j} \right)_{\phi_0} + \alpha(\phi_0) \left(\frac{\partial^2 V}{\partial \phi^k \partial \phi^j} \right)_{\phi_0} = 0. \quad (5)$$

The first term vanishes because ϕ_0 is a minimum of V . Regarding the second term, since the increment $\alpha(\phi_0)$ is nonzero, it must be

$$\left(\frac{\partial^2 V}{\partial \phi^k \partial \phi^j} \right)_{\phi_0} = 0, \quad (6)$$

which specifies the null eigenvector of the mass matrix $\partial^2 V / \partial \phi^k \partial \phi^j$ (and hence the corresponding zero-mass eigenvalue). This states the emergence of a massless field, the Goldstone mode, which can be shown to obey the Bose–Einstein statistics (Leutwyler, 1997).

In summary, the crystal lattice makes a massless field ϕ^j to arise, the Goldstone excitation associated with p^j . In the end, we expect three Goldstone bosons, one for each broken translation generator, and the ground-state symmetry is said to be spontaneously broken.¹

¹It is possible to see that apart from p , also J and K are broken generators (i.e., the system ground state is not symmetric under the corresponding transformations they generate), but it has been shown that they do not give rise to Goldstone bosons (Brauner, 2010; Brauner and Watanabe, 2014).

Pseudo-relativistic metric

A pseudo-relativistic notation can be introduced to describe Goldstone modes as sound-like four-momenta states p_μ in a locally flat manifold $\mathcal{M}$. The tangent space to any point of $\mathcal{M}$ is a four-dimensional manifold $T_{\mathcal{M}}$ with the same local pseudo-Minkowskian metric expression $\eta_{\hat{\mu},\hat{\nu}}$ as in special relativity and is referred to as the acoustic or sonic metric (Unruh, 1981; Barceló et al., 2011; Dartora and Cabrera, 2014). The space–time coordinates on $\mathcal{M}$ are expressed as $x^\mu = (c_s t, \mathbf{r})$, and the world *pseudo* means that the relevant velocity is the speed of sound c_s in the medium under consideration, which of course is not a limiting velocity.

Following this convenient formalism, instead of $T(3)$ we can consider the group of translations $T(4)$ with elements

$$U_T = 1 - \varepsilon^\mu p_\mu \quad (7)$$

on the space–time $\mathcal{M}$, where the parameters ε^μ are point dependent. The four $T(4)$ generators are $p_\mu = -i\hbar\partial_\mu$, and the crystal lattice breaks the three spatial components $p_{1,2,3}$, but not p_0 . Since $p_\mu p^\mu = 0$ (they are sound-like four-momenta in $\mathcal{M}$), a wave-like solution for them yields, as expected, the gapless dispersion relation $\omega_k = c_s k$. This relation is valid for small k and describes the Goldstone bosons as quasiparticles that are excitations of the field of lattice displacements, which are referred to as acoustic phonons.

Gauging spatial translations

The occurrence of Goldstone bosons is strongly connected to gauge theories of interactions. Weyl (1929) elevated the freedom to modify a local parameter without changing the physics of a system as a general principle known as local gauge invariance. It turns out that if a Lagrangian density $\mathcal{L}(\psi_k)$ must be invariant under the action of an element U_G of a Lie group G of local transformations $\psi_k \rightarrow U_G \psi_k$, one or more compensating fields emerge to mediate an interaction. As an example, in the description of the electromagnetism the compensating—or gauge—field is the vector potential A_μ mediating the electromagnetic interaction, and the involved gauge group is the Lie group $U(1)$ whose elements induce phase rotations on ψ_k (Mandl and Shaw, 2010).

Similar to electromagnetism or, more generally, Yang–Mills theories, it is tempting to represent acoustic phonons as gauge fields using the local (coordinate-dependent) version of U_T , that is, $U_T = 1 - \varepsilon^j(\mathbf{r})p_j$ (Jackiw, 1980; 't Hooft, 2005). The Lagrangian $\mathcal{L}$ in Eq. (2) is not invariant when U_T acts on ψ_k , despite the fact that U_T is unitary, because of the presence of spatial derivatives in the generators' expressions. The naive method of elevating $T(4)$ to the status of a gauge group in order to make $\mathcal{L}$ invariant under local spatial translations, however, is not straightforward. Given the significance of this matter, it is important to first explain why gauging a spatial translation differs significantly from gauging, for instance, the phase transformation of a wavefunction.

In electromagnetism, it is stated that an internal symmetry is gauged since the transformation only affects a phase rather than space–time coordinates. All of this has a clear geometric meaning: Referring to Fig. 1A, a fiber bundle is a space with topological structure $(\pi : \mathcal{E} \rightarrow \mathcal{M}, L, G)$, where $\mathcal{E}$ is known as total space, and for each point $P \in \mathcal{M}$, a fiber $L(P)$ is connected to P such that a neighborhood V_P of P is mapped into $\mathcal{E}$ according to $\pi^{-1}(V_P)$, and that $\pi^{-1}(V_P)$ is homeomorphic to the Cartesian product $V_P \times L$. We can also say that the total space can be written locally as a product $\mathcal{E} = \mathcal{M} \times L$. The fiber bundle is defined alongside a group G , which acts as a transformation group on the fiber and represents the various ways in which the fiber can be considered equivalent. The covariant derivative D_μ is a connection that allows a vector in $\mathcal{E}$ to be parallel-transported (Daniel and Viallet, 1980; Fré, 2013). The n -dimensional manifold $\mathcal{M}$ can also be thought of as a n -surface, with an internal space L associated with each point $P \in \mathcal{M}$ with a given topological structure. In electromagnetism, $\mathcal{M}$ is the ordinary four-dimensional space–time of special relativity, and a phase transformation on ψ_k is a vertical automorphism of the bundle and a diffeomorphism of L such that the fiber over each point

Fig. 1 (A) Scheme of a fiber bundle, a map $(\pi : \mathcal{E} \rightarrow \mathcal{M}, L, G)$, with the base space $\mathcal{M}$ and the fiber L , on which the associated group G acts. A trajectory γ in $\mathcal{M}$ is mapped to γ' in the total space $\mathcal{E}$. (B) The usual picture of a gauge theory for an internal symmetry: a gauge transformation in $\mathcal{E}$ moves the point $\pi^{-1}(P)$ to $[\pi^{-1}(P)]'$, preserving the point P on $\mathcal{M}$. Translations are defined on the base manifold $\mathcal{M}$ itself, where the gauge transformation changes the point P to P' , which prevents a straightforward definition of a fiber bundle.

in $\mathcal{M}$ remains unchanged (Fig. 1B). Since only the phase changes, the point in the total space $\mathcal{E}$ in fact moves only vertically along the fiber $L(P)$. This is the gauge freedom carried by the fiber bundle within its fibers.

By contrast, when attempting to gauge a space–time transformation group such as $T(4)$, it is clear that translations in $\mathcal{M}$ induced by $T(4)$ are horizontal diffeomorphisms of $\mathcal{M}$ (Fig. 1B, the straight arrow) since a translation by definition changes the point P in the base space, involving spatial coordinates. As a result, an invariance under the action of $T(4)$ is referred to as an external symmetry. In this context, identifying a fiber as an internal space L for which $\mathcal{E} = \mathcal{M} \times L$ locally holds is difficult, preventing a straightforward definition of a fiber bundle as $(\pi : \mathcal{E} \rightarrow \mathcal{M}, L, T(4))$.

Peculiarities of spatial translations

Gauging $T(4)$ on the pseudo-Lorentzian locally flat manifold endowed with the sonic metric and potentially suitable to describe the dynamics, propagation, and interactions of acoustic phonons appears to be mathematically similar to gauging $T(4)$ on the ordinary Lorentzian manifold of general relativity, which, however, was a difficult goal to achieve.

The groundbreaking works (Utiyama, 1956; Kibble, 1961; Sciama, 1964) followed the Yang–Mills formalism and defined the covariant derivative as $D_{\hat{v}} = \partial_{\hat{v}} + W_{\hat{v}}$. Here $W_{\hat{v}}$ is a gauge field that, when written in terms of its components $R_{\hat{v}}^{\mu}$, reads

$$W_{\hat{v}} = R_{\hat{v}}^{\mu} p_{\mu}. \quad (8)$$

Employing Eq. (8), $D_{\hat{v}}$ was written as

$$D_{\hat{v}} = h_{\hat{v}}^{\mu} \partial_{\mu} \quad (9)$$

where

$$h_{\hat{v}}^{\mu} = \delta_{\hat{v}}^{\mu} - i\hbar R_{\hat{v}}^{\mu}. \quad (10)$$

If the covariant index $\hat{v}$ is a local Lorentz index, the field $h_{\hat{v}}^{\mu}$ defines a set of four orthonormal vectors $h_{\hat{v}}^{\mu} \partial_{\mu}$, the tetrad or vierbein. After a partial success of this still unsatisfactory formulation, Cho (1976) developed a gauge theory of translations with a Yang–Mills-type Lagrangian in which the gauge potentials were correctly interpreted as connections (in particular, they are the nontrivial part of the vierbein fields $h_{\hat{v}}^{\mu}$). D. Gensing and G. Gensing reached similar conclusions (Gensing and Gensing, 1983), obtaining the gauging of the Poincaré group in a form that allowed the general relativity to be expressed as a gauge theory of $T(4)$. More recently, the Yang–Mills theory of the affine group was developed (Tresguerres and Mielke, 2000; Martín-Martín and Tiemblo, 2010), where tetrads have been identified with nonlinear connections, for which the given $h_{\hat{v}}^{\mu} \partial_{\mu}$ expression is a simplified yet correct version of the general formulation.

These concepts were developed to describe gravity, which is now correctly formulated as a Yang–Mills theory. Nonetheless, the same formulation holds and can be used to develop a Yang–Mills theory of elasticity in solid crystals by considering the crystal lattice manifold $\mathcal{M}$, its metric $g_{\mu\nu}$, and its pseudo-Minkowski tangent space $T_{\mathcal{M}}$ equipped with the sonic metric $\eta_{\hat{\mu}\hat{\nu}}$ instead of the ordinary space–time. In this case, the field components $R_{\hat{v}}^{\mu}$ correspond to the tensor components of the crystal elasticity field, whereas in gravity theory they correspond to the Ricci tensor (Weinberg, 1972). This allows to formulate the physics of lattice vibrations in crystals (acoustic phonons) in a way that results somehow similar to the physics of gravitational waves in the ordinary space–time, as described in part by Dartora and Cabrera (2014), developed in more detail by the author of the present work (Vallone, 2019), and shortly discussed in Section “Yang–Mills theory of acoustic phonons in crystal.”

Yang–Mills theory of acoustic phonons in crystal

The infinitesimal displacement of the crystal lattice induces a local translation $\psi_k(x^{\mu}) \rightarrow \psi'_k(x^{\mu}) = U_T(x^{\mu})\psi_k(x^{\mu})$ on the electronic wavefunction. Let us define a gauge-covariant derivative $D_{\hat{v}} = h_{\hat{v}}^{\mu} \partial_{\mu}$, with $T(4)$ as gauge group. Following the standard gauge prescriptions, all ordinary derivatives in the Lagrangian must be replaced by $D_{\hat{v}}$, and the field $W_{\hat{v}}$ must transform in turn according to $W_{\hat{v}} \rightarrow W'_{\hat{v}} = U_T W_{\hat{v}} U_T^{\dagger} - (\partial_{\hat{v}} U_T) U_T^{\dagger}$, which implies

$$(D_{\hat{v}} \psi_k)' = U_T (D_{\hat{v}} \psi_k), \quad (11)$$

a position that makes the Lagrangian gauge invariant under the local action of $T(4)$.

The translational symmetry is manifested by the appearance of conserved currents j_{μ} according to the Noether theorem. In the present case, the relevant gauge charges are the three generators $p_k = \int d^3x j_k(x) = \int d^3x T_{0k}(x)$ of the spatial translations, whose corresponding currents are the components of the symmetric energy–momentum tensor T_{0k} . Moreover, the total energy operator (Hamiltonian) $H = \int d^3x c_s^2 T_{00}(x)$ is written in terms of p_0 , the unbroken generator of the translations in the time coordinate.

An essential difference from electromagnetism is the fact that the elements of $T(4)$ do not commute, even if the group generators commute on a flat space–time, $[p_{\hat{\mu}}, p_{\hat{v}}] = 0$. Indeed, if $U_T(x)$ and $U_T(y)$ are two elements of $T(4)$, then it holds

$$[U_T(x), U_T(y)] = -\hbar^2 [\varepsilon^{\mu}(x) \partial_{\mu} \varepsilon^{\nu}(y) - \varepsilon^{\mu}(y) \partial_{\mu} \varepsilon^{\nu}(x)] \partial_{\nu}. \quad (12)$$

The intrinsic difference between the structure of the global and the local version of $T(4)$ can be expressed more formally by writing the algebra of currents

$$[j_\mu(x), j_\nu(y)] = -i\hbar \left(\partial_\mu j_\nu(y) - \partial_\nu j_\mu(x) \right) \delta^3(x - y), \quad (13)$$

where the commutator is in general nonzero for $x \neq y$, which makes the local form of the gauge group non-Abelian. Finally, the algebra of generators can be written as in [Gegenberg et al. \(2016\)](#)

$$[p_\mu, p_\nu] = ig f_{\mu\nu}^i p_i \quad (14)$$

where $f_{\mu\nu}^i$ are the structure constants and g is the coupling constant of the theory, with $f_{\mu\mu}^i = 0$ and $f_{\mu\nu}^i = -f_{\nu\mu}^i = 1$ for $\mu \neq \nu$. In a flat space-time like $T_{\mathcal{M}}$, it is $[p_\mu, p_\nu] = 0$, but this is not true for $\mathcal{M}$. This is a central point of the theory, and the non-Abelianity of the local symmetry expressed by the algebra of Eq. (14) is responsible for the phonon-phonon interactions. On this basis it follows also

$$[W_{\hat{\mu}}, W_{\hat{\nu}}] = ig f_{\beta\gamma}^\alpha R_{\hat{\mu}}^\beta R_{\hat{\nu}}^\gamma p_\alpha. \quad (15)$$

Making use of Eq. (9), the commutator $[D_{\hat{\mu}}, D_{\hat{\nu}}]$ can be written in the alternative forms

$$[D_{\hat{\mu}}, D_{\hat{\nu}}] = G_{\hat{\mu}\hat{\nu}}^\alpha p_\alpha = G_{\hat{\mu}\hat{\nu}} \quad (16)$$

where the field strength tensor $G_{\hat{\mu}\hat{\nu}}$ and its components $G_{\hat{\mu}\hat{\nu}}^\alpha$ are given by

$$\begin{aligned} G_{\hat{\mu}\hat{\nu}} &= \partial_{\hat{\mu}} W_{\hat{\nu}} - \partial_{\hat{\nu}} W_{\hat{\mu}} + [W_{\hat{\mu}}, W_{\hat{\nu}}] \\ G_{\hat{\mu}\hat{\nu}}^\alpha &= \partial_{\hat{\mu}} R_{\hat{\nu}}^\alpha - \partial_{\hat{\nu}} R_{\hat{\mu}}^\alpha + ig f_{\beta\gamma}^\alpha R_{\hat{\mu}}^\beta R_{\hat{\nu}}^\gamma. \end{aligned} \quad (17)$$

It is worth noting that Eq. (17) resembles expressions typical of classical Yang-Mills theories, although it should be remembered that the symmetry group governs an external symmetry and the gauge field $W_{\hat{\mu}}$ contains spatial partial derivatives since the infinitesimal group generators act as differential operators.

The Lagrangian density for the free gauge field is

$$\mathcal{L}_R = \frac{1}{4} G_{\hat{\mu}\hat{\nu}}^\alpha G_{\hat{\mu}\hat{\nu}}^\alpha, \quad (18)$$

that explicitly reads

$$\mathcal{L}_R = \frac{1}{2} \left(\partial_{\hat{\mu}} R_{\hat{\nu}}^\alpha \partial^{\hat{\mu}} R_{\hat{\nu}}^\alpha - \partial_{\hat{\mu}} R_{\hat{\nu}}^\alpha \partial^{\hat{\nu}} R_{\hat{\mu}}^\alpha \right) + ig f_{\alpha}^{\delta} R_{\hat{\nu}}^\delta \left(\partial_{\hat{\mu}} R_{\hat{\nu}}^\alpha \right) - \frac{g^2}{4} f_{\beta\gamma}^\sigma f_{\sigma}^{\delta\epsilon} R_{\hat{\mu}}^\beta R_{\hat{\nu}}^\gamma R_{\hat{\delta}}^\delta R_{\hat{\epsilon}}^\epsilon \quad (19)$$

and describes the dynamics of a field with cubic and quartic (self-interacting) terms. Writing the Euler-Lagrange equation

$$\partial^{\hat{\mu}} \frac{\partial \mathcal{L}_R}{\partial (\partial^{\hat{\mu}} R_{\hat{\nu}}^\alpha)} = \frac{\partial \mathcal{L}_R}{\partial R_{\hat{\nu}}^\alpha} \quad (20)$$

and imposing the Lorenz gauge (that allows for great simplification of all the expressions), the equation of motion for the free fields $R_{\hat{\nu}}^\alpha$ results (defining $\lambda = g^2$ and $\square = \partial_{\hat{\mu}} \partial^{\hat{\mu}}$) in

$$\square R_{\hat{\nu}}^\alpha + \lambda f_{\beta\gamma}^\sigma f_{\sigma}^{\delta\epsilon} R_{\hat{\mu}}^\beta R_{\hat{\nu}}^\gamma R_{\hat{\delta}}^\delta = 0. \quad (21)$$

This equation does not contain any mass term (it would be a linear term in $R_{\hat{\nu}}^\alpha$), but a cubic self-interacting term is present, coming from the quartic term in the Lagrangian.

All components are strongly coupled and difficult to handle. To understand the underlying physics, it is particularly interesting to consider in more detail the case of a simple one-dimensional atomic chain along x . Here we assume—without loss of generality—that the perturbation is along the longitudinal direction (longitudinal acoustic phonon), that is, $R_0^0 = 0$. From the group commutation rules in Eq. (14), the equations of motion for the nonzero field components $\hat{R} = R_0^1$ (the longitudinal acoustic phonon field) and $\hat{S} = R_1^1$ (the spatial strain field) decouple, yielding

$$(\partial_t^2 - c_s^2 \partial_x^2) \hat{R} + \lambda c_s^2 |\hat{R}|^2 \hat{R} = 0 \quad (22)$$

$$(\partial_t^2 - c_s^2 \partial_x^2) \hat{S} = 0. \quad (23)$$

$\hat{S}(x, t)$ describes the fluctuations of the crystalline strain field (coupled to phonons in higher dimensional domains, and which can be scattered by them). Concerning the equation for the acoustic phonon field $\hat{R}(x, t)$, the parameter λ leads to a nonlinear oscillatory solution for $\hat{R}$ with a dispersion relation given by ([Frasca, 2011, 2017](#))

$$\omega_k^2 = \sqrt{\frac{\lambda c_s^2}{2}} \rho_R^2 + c_s^2 k^2 \quad (24)$$

where ρ_R is an integration constant that depends on cell properties. Eq. (22) can be promptly derived by the Euler–Lagrange equation from a Lagrangian that is a simplified form of Eq. (19),

$$\mathcal{L}_R = \frac{1}{2} \left(\eta^{\mu\nu} \partial_\mu \hat{R} \partial_\nu \hat{R} - \frac{1}{2} \lambda \hat{R}^4 \right), \quad (25)$$

the well-known Lagrangian with ϕ^4 -potential describing a massless self-interacting scalar field (Mandl and Shaw, 2010).

To summarize, apart from their description as Goldstone bosons, acoustic phonons can also be viewed as gauge bosons mediating lattice interactions, described in terms of a non-Abelian gauge theory. The local gauge invariance imposed on the Lagrangian in Eq. (2) gives rise to three gauge fields identified with acoustic phonon modes, one longitudinal and two transverse. Their Lagrangian is Eq. (19), for which a simplified one-dimensional form is Eq. (25), which describes phonon–phonon interactions by the nonlinear (quartic) term proportional to λ , a feature that arises from the commutator $[W_{\hat{\mu}}, W_{\hat{\nu}}]$ in the field strength tensor, which is not zero.

It is worthwhile to consider that Eq. (24) reduces to the well-known Debye form (Ashcroft and Mermin, 1976) $\omega_k = c_s |k|$, provided the nonlinear term in the Lagrangian can be neglected. However, a relevant and rather unexpected result is that ω_k is gapped in its general form due to self-interactions when the latter are relevant (i.e., $\omega_k \neq 0$ in the limit $k \rightarrow 0$), even though the gauge field remains massless (see a more extended discussion in Vallone (2019)).

As a side feature already noticed by Dartora and Cabrera (2014), the commutator $[D_{\hat{\mu}}, D_{\hat{\nu}}]$ satisfies a cyclic identity that can be written as

$$D_{\hat{\sigma}} G_{\hat{\mu}\hat{\nu}} + D_{\hat{\nu}} G_{\hat{\sigma}\hat{\mu}} + D_{\hat{\mu}} G_{\hat{\nu}\hat{\sigma}} = 0, \quad (26)$$

an equation known as the Bianchi identity for the field strength tensor. The tensor $R_{\hat{\mu}}^{\nu}$ plays the same role as the Ricci tensor in general relativity and obeys the same dynamical equations implied by Eq. (26). It describes the local perturbation of the sonic metric $\eta_{\hat{\mu}\hat{\nu}}$ of the solid crystal caused by the propagation of an acoustic phonon, in strict analogy to the space–time Lorentz metric perturbation induced by the propagation of a gravitational wave as described in general relativity.

Optical phonons remain still undescribed

In the previous considerations, optical phonons were never considered. Nevertheless, they play a central role in semiconductor physics, as they can support Auger recombinations, describe the carriers relaxation, and are crucial for understanding quantum transport and carriers capture in quantum-confined heterostructures (Vallone, 2010, 2013). However, they do not arise from the breaking of translational symmetry or as gauge modes described so far.

We recall that for several binary compounds of interest in electronics, such as GaAs, InP, and GaN, the crystal can be viewed as composed of two interacting sublattices, one for each atomic species. Textbook toy models describe the relevant physics considering a one-dimensional Bravais lattice with two ions per unit cell. Considering it as a set of elementary classical oscillators, one can show that two different modes of oscillation exist (Ashcroft and Mermin, 1976):

- (a) the two atoms in the cell oscillate at frequency ω_k around their equilibrium position with the same direction and phase, Fig. 2A, leaving their relative displacement σ_d unchanged. The perturbation is the acoustic mode, an elastic wave propagating in the lattice with the speed of sound c_s , and the corresponding collective excitation is the acoustic phonon. Its dispersion relation has an expression that can be approximated in the long-wavelength limit as $\omega_k = c_s |k|$, indicating that the acoustic mode can be excited with arbitrarily small energy (there is no gap in ω_k);

Fig. 2 Acoustic (A) and optical (B) oscillation modes of a two-atom elementary cell. In (C), the modes dispersion ω_k .

(b) conversely, the two atoms in the cell oscillate with respect to each other, Fig. 2B, and their relative displacement $\sigma(t)$ oscillates about an equilibrium position along a well-defined direction with respect to a reference frame, defining an oscillating dipole moment of the cell when the solid is ionic. This is the optical mode, and the associated collective excitation is the optical phonon, whose role in semiconductor transport theory and electron dynamics is of great importance. It has been shown that $\omega_{k \rightarrow 0} \rightarrow \omega_0 \neq 0$: in other words, the optical phonon dispersion ω_k is gapped, and the excitation of the optical mode costs a fixed energy $\hbar\omega_0$, which is nonzero even for $k \rightarrow 0$, see Fig. 2C.

Section “Spontaneous symmetry breaking and order parameter” shows that the concept of SSB allows a unified description of the two phonon modes. To follow this path, in the next section we will first describe what is meant by spontaneous symmetry breaking in general. We will then discuss how this concept can be applied to acoustic and optical phonons in solid-state physics.

Spontaneous symmetry breaking and order parameter

A system consisting of a sphere that is free to move on the underside of a paraboloid can remain in a stable equilibrium state, as in Fig. 3A. A small displacement would cause the sphere to return to the bottom of the paraboloid, that is, to its equilibrium state, regardless of the displacement direction.

In quantum field theory, we can consider an electron instead of a sphere, and the paraboloid can represent a potential energy profile whose vertex lies at the origin of a reference frame. In its simplest formulation, the dynamics of the system can be described by a complex scalar field ϕ and a potential energy profile $V(\phi) = \phi^* \phi$, whose only minimum is in $\phi = 0$. The ground state $|\psi_0\rangle$ of the system is a stable vacuum state.

We can now introduce an operator $\hat{\phi}$ corresponding in coordinates to the field ϕ (in elementary quantum mechanics it corresponds to the position operator). In this very simple example this operator is not very useful, but we can easily notice that its expectation value on the vacuum state is $\langle\psi_0|\hat{\phi}|\psi_0\rangle = \langle\hat{\phi}\rangle = 0$. This operator is called order parameter, and its zero expectation value expresses the concept that the system is in a symmetric (i.e., not ordered) state. The Lagrangian density for the scalar field ϕ moving in the potential $V(\phi)$ is $\mathcal{L} = \partial_\mu \partial^\mu \phi - V(\phi)$ and it is $U(1)$ invariant, that is, it is invariant for $\phi \rightarrow e^{i\theta}\phi$, and the same invariance holds for the state $|\psi_0\rangle$.

As shown in Fig. 3B, the situation is quite different if we assume that the paraboloid suddenly becomes a Mexican hat because of some phase transition: its vertex $\phi = 0$ no longer represents an equilibrium position for the sphere in classical terms, and even a slight perturbation leads to the sphere falling into the brim of the hat. The sphere can move along the brim without spending energy,

Fig. 3 (A) The sphere in the paraboloid origin is in a stable equilibrium ground state. (B) For a Mexican hat-shaped potential $V(\phi)$, the origin is no more a stable state. Conversely, stable ground states are the infinitely degenerate states $|\psi_j\rangle$ into the brim. However, a nonzero order parameter arises.

whereas a small perturbation that makes the sphere climb the hat crown costs a certain amount of energy. As a result, the sphere tends to return to the brim.

Coming back to the quantum world, the Mexican hat potential can be written as $V(\phi) = -a(\phi^* \phi) + b(\phi^* \phi)^2$ with a and b positively defined real parameters. A possible vacuum state corresponds to $\langle \hat{\phi} \rangle = 0$, which has $U(1)$ symmetry as well as the Lagrangian, but it is not the ground state of the system. Therefore, the system will spontaneously decay into a specific stable ground state $|\psi_j\rangle$.

In this different situation, the expectation value of $\hat{\phi}$ on the new vacuum state is $\langle \hat{\phi} \rangle = \sqrt{a/2b} e^{i\theta_j}$ for a given real θ_j between 0 and 2π . Since $\mathcal{L}$ is symmetric with respect to a rotation $\hat{U}$, but $|\psi_j\rangle$ is not, the $U(1)$ symmetry has been broken, and a SSB has occurred, because of the choice of a particular θ_j . Moreover, a small translation around the hat brim consists of a transition between two stable degenerate ground states, and it does not cost energy. In contrast, a small shift in the orthogonal direction costs energy, and this has profound consequences.

It is important to emphasize that we found for $\langle \hat{\phi} \rangle$ a value of zero in the symmetric state, and a nonzero value for each broken-symmetry states. This is what characterizes the order parameter operator, whose eigenvalues in the broken $U(1)$ symmetry phase are the couples $\langle \hat{\phi} \rangle = (\phi_0, \theta_j)$, where $\phi_0 = \sqrt{a/2b}$ is the radius of the hat brim and θ_j is an angle measured with respect an arbitrary reference direction.

Ginzburg–Landau approach and SSB

As indicated in Introduction, the concept of SSB was first formulated in the context of condensed matter physics by Ginzburg and Landau in a paper on superconductivity (Landau, 1965). In a completely different context, Higgs (1964) started by writing a gauge-invariant Lagrangian density containing a potential showing a spontaneous breakdown of the $U(1)$ (rotational) symmetry. We should follow in the footsteps of Ginzburg and Landau.

When they studied superconductivity, they considered a complex scalar field with continuous $U(1)$ invariance in the symmetric normal (i.e., not superconducting) phase. A phase transition from the normal to superconducting state breaks the phase rotation symmetry. The ordering transition can be described by the Landau free energy functional for the complex order parameter ϕ as

$$F(\phi) = -\frac{\mu_0^2}{2}(\phi\phi^*) + \frac{\lambda}{4}(\phi\phi^*)^2 + O(|\phi|^6), \quad (27)$$

where μ_0^2 and λ are real and positively defined parameters. The microscopic origin of $U(1)$ symmetry breaking appeared only some years later, thanks to the work of Bardeen, Cooper, and Schrieffer (BCS theory) (Bardeen et al., 1957a, b): phonons mediate an attractive interaction between electrons, and the simplest scalar state that can be constructed from an electron pair with total spin zero is $|\psi\rangle = c_{\mathbf{k}\uparrow}^\dagger c_{-\mathbf{k}\downarrow}^\dagger |0\rangle$, where $c_{\mathbf{k}\uparrow}^\dagger$ creates from the vacuum an electron state with wavevector $\mathbf{k}$ and the arrow represents the electron spin state. The interaction term in the Hamiltonian $H_{\text{BCS}} \propto c_{\mathbf{k}\uparrow}^\dagger c_{-\mathbf{k}\downarrow}^\dagger c_{\mathbf{k}\downarrow} c_{-\mathbf{k}\uparrow}$ is locally gauge invariant with $U(1)$ as gauge group with parameter θ transforming $|\psi\rangle$ into $e^{i\theta(x)}|\psi\rangle$. However, in the mean field approximation, the interaction term becomes $\hat{H}_{\text{BCS}} \propto \Delta_{\mathbf{k}} c_{\mathbf{k}\uparrow}^\dagger c_{-\mathbf{k}\downarrow}^\dagger + \Delta_{\mathbf{k}}^* c_{\mathbf{k}\downarrow} c_{-\mathbf{k}\uparrow}$, and the continuous $U(1)$ symmetry is broken since only the special values $\theta = 0$ and $\theta = \pi$ make $\hat{H}_{\text{BCS}}$ gauge invariant. Here $\Delta_{\mathbf{k}}$ is the energy gap of the Cooper pair (Bardeen et al., 1957a, b), the superconducting phase is the ordered phase, and, in particular, Gor'kov and Melik-Barkhudarov (1964) showed that a rigorous microscopic evaluation of $\hat{H}_{\text{BCS}}$ provides the expression for the Ginzburg–Landau free energy in Eq. (27), with $\Delta_{\mathbf{k}}$ as the order parameter.

Eq. (27) also describes other quantum phase transitions, for example, in materials changing from a paramagnetic (disordered) to a ferromagnetic (ordered) phase when the system temperature T falls below the Curie temperature. In this case, the field ϕ —the order parameter—is the magnetization, and in the ordered phase, the system chooses a particular spatial direction along which the atomic spins self-align. The system is no longer $U(1)$ -invariant. In these materials, the Higgs and Goldstone modes correspond respectively to the modulation of the amplitude and phase of the magnetization, the order parameter that emerges when the continuous rotational symmetry is broken.

SSB in crystalline solids

The expansion of the total energy of crystal atoms with mass μ_n around their equilibrium positions, displaced by $\vec{a}_n$ at temperature T , can be written as

$$E = \frac{1}{2} \sum_n \mu_n \left(\partial_t a_n^i \right)^2 + \sum_{nm} \sum_{\vec{ij}} Q_{nm;\vec{ij}} a_n^i a_m^j + \sum_{nmqr} \sum_{\vec{ijkl}} R_{nmqr;\vec{ijkl}} a_n^i a_m^j a_q^k a_r^l + \dots, \quad (28)$$

where the sum runs over the N atoms index $n \in \{1^i, 1^j, 1^k, \dots, N^i, N^j, N^k\}$, and a_n^i are the spatial components of $\vec{a}_n$. The first term is the kinetic energy of the atoms and the second term is the potential harmonic term, followed by the fourth-order anharmonic term. In the harmonic approximation, the $Q_{nm;\vec{ij}}$ matrix represents the energy cost associated with moving atoms from their equilibrium position. In a field-theoretic approach, the displacements are defined by a complex vector field $\vec{\phi}$, and the free energy can be conveniently written in terms of the spatial components of $\vec{\phi}$ as

$$F(\phi) = \frac{1}{2!} Q_{ij} \phi^i \phi^j + \frac{1}{4!} R_{ijkl} \phi^i \phi^j \phi^k \phi^l + O(|\phi|^6), \quad (29)$$

where

$$Q_{ij} = \frac{\partial^2 F(\phi)}{\partial \phi^i \partial \phi^j}, \quad R_{ijkl} = \frac{\partial^4 F(\phi)}{\partial \phi^i \partial \phi^j \partial \phi^k \partial \phi^l} \quad (30)$$

are evaluated at equilibrium. More generally, and considering a three-dimensional crystal, we can rewrite the Eq. (29) in a more compact way as

$$F(\phi) = \frac{1}{2} \mathcal{A} \phi^* \phi + \frac{1}{4} \mathcal{B} (\phi^* \phi)^2 + O(|\phi|^6), \quad (31)$$

where $\mathcal{A}$ and $\mathcal{B}$ are real coefficients and the complex field ϕ is an atomic displacement matrix whose rank and symmetry properties depend on the unitary cell under consideration (Vaks and Khromov, 2008). It should be noted that odd powers of ϕ are usually excluded in the free energy expansion. This is because the free energy cannot contain a phase, in order to be an observable. This choice does not prevent important interactions from occurring (such as the coupling of three phonons and the decay of phonons), and this important point will be clarified at the end of this section.

In our discussion we consider the transition from a parent (*bcc*, symmetric) and a product (*hcp*, with broken symmetry) crystalline phase. It is worth mentioning that in the framework of Ginzburg and Landau theory, the difference of their free energy $F(\phi)$ was calculated in Sanati et al. (2001) as

$$\tilde{F}(\phi) = \frac{A_0(T - T_0)}{2} \phi^2 + B\phi^4 + C\phi^6, \quad (32)$$

where ϕ is a scalar order parameter (the same arguments would of course apply to the structural transition between *fcc* and *hcp* phases). $\tilde{F}(\phi)$ was derived from a one-dimensional (or scalar) model and has the same functional form as the Eq. (31), except that the expansion in powers of ϕ also retains the sixth-order term. Here T_0 is a characteristic temperature, and A_0 and C are real and positively defined parameters, while B is negative. Moreover, it can be observed that for $T < T_0$, also the coefficient of ϕ^2 is negative.

The Ginzburg and Landau theory, and even the Higgs mechanism, have no intrinsic constraints on the number of expansion terms of $F(\phi)$ in powers of ϕ since both theories are phenomenological and provide a way to describe global symmetry breaking, that is, a second-order transition, at least in their original formulations. Nevertheless, the same theory can be applied to first-order structural phase transitions (Krumhansl, 1992), for which an expansion to the sixth-order is customary, when an accurate free energy fit and a description of the behavior around T_0 are required. However, this is not the focus of the present discussion: the main requirement for the present phenomenological approach is to correctly describe the SSB, that is, the properties of the structural phase for $T \ll T_0$ and for $T \gg T_0$. Nevertheless, an extensive discussion about this point can be found in Vallone (2020), where it is shown that the functional $F(\phi)$ given by the Eq. (27) correctly describes the SSB occurring during a crystalline phase transition, provided we identify the coefficients according to

$$-\mu_0^2 = A_0(T - T_0), \quad \frac{\lambda}{4} = B, \quad (33)$$

with $T < T_0$, $A_0 > 0$, $B > 0$, hence $\lambda > 0$.

Exploiting the similarities between the sonic metric and the Lorentzian metric of ordinary spacetime, the dynamics of ϕ can be described by the Lagrangian density

$$\mathcal{L}_\phi = \frac{1}{2} \partial_\mu \phi^* \partial^\mu \phi - V(\phi) \quad (34)$$

$$V(\phi) = -\frac{\mu_0^2}{2} \phi^* \phi + \frac{\lambda}{4} (\phi^* \phi)^2 + V_c(\phi), \quad (35)$$

where the potential energy $V(\phi)$ has been identified with the crystal free energy in the *hcp* phase supplied by $F(\phi)$. We have included in the potential an additional term $V_c(\phi)$ which depends on the particular crystal we are considering. For example, in a cubic crystal it is (Plischke and Bergersen, 2006) $V_c(\phi) = \lambda_1 [\text{Re}(\phi) \text{Im}(\phi)]^2 = \lambda_1 / 4 (\phi^* \phi)^2 \sin^2(\text{arctan}(\phi))$, where $n = 2$ and λ_1 is a constant. $V_c(\phi)$ provides four pairs of minima and maxima in the potential brim, corresponding to ion positions. In hexagonal crystals $n = 3$, there are six pairs of local minima and maxima, but this is only a minor detail. What matters is the Mexican hat shape of $V(\phi)$, which is typical of the Higgs SSB theory, slightly modified by the $V_c(\phi)$ term (Fig. 4A).

In the neighborhood of $\phi = 0$, the Lagrangian $\mathcal{L}_\phi$ is still $U(1)$ invariant, but its symmetric vacuum state is unstable. When $\lambda_1 = 0$, all ϕ values on the circle of radius $\phi_0 = \sqrt{\mu_0^2/\lambda}$ are minima, and the brim is flat. The order parameter takes nonzero values here, and the only stable vacuum states are those characterized by an order parameter expectation value $\langle \hat{\phi} \rangle = \phi_0 e^{i\theta}$. Among them, the system chooses the ordered state for which θ has a given value θ_j , and this fixes the true vacuum state of the system. Therefore, the vacuum is not $U(1)$ -invariant since the rotational symmetry described by the Lie group $U(1)$ is broken: the value θ_j fixes the expectation value of the order parameter ϕ .

Fig. 4 (A) The Higgs potential $V(\phi)$, leading to the excitation of the amplitude (or Higgs) and phase (or Goldstone) modes, σ and θ , for the hcp phase. (B) Illustrative scheme of bcc , fcc , and hcp crystal structures (the dots represent the ions).

The Higgs SSB formalism, as well as the identification of $U(1)$ as the symmetry group for the Lagrangian, indicates that there is also a more fundamental reason for the selection of the quartic expression $F(\phi)$ of Eq. (27) as an appropriate potential, instead of a more complicated sixth-order expression. It is possible to demonstrate a theorem (Michel and Radicati, 1971; Brauner, 2010), according to which, if G is a compact Lie group (in the present case, $U(1)$) that acts smoothly on the real manifold $\mathcal{M}$ with $\phi \in \mathcal{M}$, the orbit $\mathcal{G}(\phi)$ is critical, that is, every smooth real $\mathcal{G}$ -invariant function on $\mathcal{M}$ is stationary on $\mathcal{G}(\phi)$ if and only if $\mathcal{G}(\phi)$ is isolated in its stratum (a stratum consists of all points of the same symmetry class). Very shortly and informally, we remind that an orbit $\mathcal{G}(\phi)$ is the ensemble of all points of $\mathcal{M}$ which can be reached from ϕ via a (eventually broken) symmetry transformation, that is, $\mathcal{G}(\phi) = \{g\phi | g \in G\}$. Two points on the same orbit have isotropy groups H_ϕ that are isomorphic (the isotropy group H_ϕ is formed by the set of all group elements that leave ϕ invariant, i.e., $H_\phi = \{g\phi = \phi | g \in G\}$: it is formed by those transformations that are left unbroken when the order parameter takes the value ϕ). Any potential V on the manifold $\mathcal{M}$ that is invariant under the group action, that is $V(\phi) = V(g\phi)$ for all $\phi \in \mathcal{M}$ and $g \in G$, can therefore be viewed as functions on the orbits: thus, the minimization of a given potential $V(\phi)$ can be reformulated as a minimization of a function on the space of orbits, where a transformation $\phi \rightarrow g\phi$ along one orbit does not require energy: this is the origin of the Goldstone boson. Changing orbit requires an energy cost, which will give rise to the Higgs boson, for which a mass term is expected. An interesting fact for our discussion is that (Brauner, 2010) *the theorem makes no particular assumption about the form of the invariant function, so it may be a Higgs-type quartic potential as well as the full quantum effective potential whose power expansion may contain terms of arbitrarily high orders in ϕ .*

With reference to Fig. 4A, we can expand $\mathcal{L}_\phi$ around the vacuum (ϕ_0, θ_j) in terms of small oscillations σ and θ , obtaining the Lagrangian density

$$\mathcal{L}_{\sigma\theta} = \frac{1}{2} \left(\partial_\mu \theta \partial^\mu \theta - \frac{\lambda \theta^4}{2} \right) + \frac{1}{2} \left(\partial_\mu \sigma \partial^\mu \sigma - 2\mu_0^2 \sigma^2 - 2\mu_0 \sqrt{\lambda} \sigma^3 - \frac{\lambda \sigma^4}{2} \right) - \mu_0 \sqrt{\lambda} \sigma \theta^2 - \frac{\lambda}{2} \theta^2 \sigma^2 + \frac{\lambda}{4} (\sigma^2 + \theta^2) \theta^2, \quad (36)$$

that can be simplified neglecting nonlinear terms higher than second order:

$$\mathcal{L}_{\sigma\theta} = \frac{1}{2} \partial_\mu \theta \partial^\mu \theta + \frac{1}{2} \partial_\mu \sigma \partial^\mu \sigma - \mu_0^2 \sigma^2. \quad (37)$$

Eq. (37) provides two oscillatory solutions for the fields θ and σ when plugged into the Euler-Lagrange equations. The solution of θ is a Nambu-Goldstone mode with frequency dispersion relation $\omega_\theta^2 = c_s^2 k^2$, and it is a phase oscillation mode along the Mexican

hat brim. Because there is no mass term, the dispersion relation is gapless. The solution for σ describes amplitude oscillations and is a Higgs mode, whose frequency dispersion relation is $\omega_\sigma^2 = 2\mu_0^2 + c_s^2 k^2$. It is gapped because the Lagrangian contains the mass term $\mu_0\sqrt{2}$.

The field θ is a pure gauge field associated with the acoustic phonon in the lattice, which breaks continuous translational invariance because of the lattice itself. Since the ground state of θ may be changed by simply executing a gauge transformation along the valley of the Mexican hat, it is a massless Goldstone mode. Moreover, the Higgs mode can be identified with the optical phonon, whose frequency in the long-wavelength limit is given by the mass-like term, $\omega_0 = \mu_0\sqrt{2}$.

Eq. (36) also describes multiphonon scattering terms and phonon decay (the terms proportional to $\theta^2\sigma^2$, σ^3 , σ^4 , θ^4 , and $\sigma\theta^2$). All these effects can be significant in systems where phonons are strongly coupled to the strain field. As an example, retaining the term in $\sigma\theta^2$ (i.e., the nonlinear term at the lowest order in σ), the Lagrangian describes the acousto-optical phonon coupling, and the resulting frequency dispersion relation is shown in Fig. 5, characterized by the opening of minigaps in the acoustic branch ω_θ (Duggen and Willatzen, 2017; Xie, 2022). The result was obtained by solving numerically the wave equations arising from Eq. (36) at the lowest order in λ and approximating ω_σ with ω_0 (see Vallone, 2019, for details).

Experimental evidences of SSB in structural phase transitions in metals

Observations of the experimental phonon dispersion of Co at room temperature and at 833 K (Wakabayashi et al., 1982; Strauss et al., 1996) confirm the existence of optical phonon branches only at the lowest temperatures.

In contrast to high energy physics, it is quite easy to restore hidden symmetry; all that is required is to raise the temperature above the value of T_0 of the crystal under consideration (in our example, Zr, Ti, and Co). In the symmetric phase, a structural phase transition $hcp \rightarrow (bcc, fcc)$ occurs, and the coefficient of the quadratic term in Eq. (27) becomes positive. The system has recovered the $U(1)$ invariance that was lost in the hcp , and the expectation value of $\hat{\phi}$ in the stable vacuum state is now $\langle \hat{\phi} \rangle = 0$. The only broken continuous symmetry is translational invariance, which still allows for the emergence of the acoustic phonon, the Nambu–Goldstone mode. However, there is no Higgs mode in Co at $T = 833$ K (Strauss et al., 1996), where the structural phase changes to bcc and only the acoustic phonon branch remains. Similar considerations and experimental results can be found in literature for Zr and Ti ($fcc \rightarrow hcp$) (Stassis et al., 1979; Wakabayashi et al., 1982; Strauss et al., 1996; Schnell et al., 2006; Purja and Mishin, 2012; Grimvall et al., 2012). Even though it is a much simpler formulation, the hidden symmetry restoration represented by the $hcp \rightarrow (bcc, fcc)$ phase transition when temperature increases above T_0 is conceptually similar to what occurs in the Standard Model for the electroweak interaction above the electroweak symmetry breaking energy (≈ 159 GeV (D’Onofrio and Rummukainen, 2014)).

The number of oscillating modes for θ and σ depends on the crystal unitary cell, and on the dimension of the matrix associated with the operatorial form of the order parameter $\hat{\phi}$. In the considered examples, the crystal broken phase is hcp , and it is possible to write the displacement matrices Q evaluated at symmetry points of the Brillouin zone. They can be employed to build the dynamical matrix as blocks of submatrices, substantially the Q themselves. The dynamical matrix has six eigenvalues, and so it is for $\hat{\phi}$ at the same symmetry points. In the ground state of the broken phase, there will be three eigenvalues belonging to θ and three belonging to σ . Hence, there will be three fields θ (acoustic branches) and three fields σ (optical branches). For each branch, two fields represent oscillations in the hcp basal plane (transversal modes), and one field represents an oscillation orthogonal to the plane (longitudinal mode).

As an aside, even if one has conceptually identified free energy with the Higgs potential, it is generally not possible to assign a particular type of phonon to the Higgs and Goldstone modes (Meier et al., 2019). Since $Q_{n,m}$ is the matrix of the force constant, its

Fig. 5 The nonlinear coupling between Goldstone and Higgs modes, which gives origin to acousto-optic coupling.

value depends on the atomic masses in the unit cell, and the phonons are eigenvectors of $Q_{n,m}/\sqrt{\mu_n\mu_m}$, which, according to our description, correspond to the Goldstone and Higgs modes only when the crystal contains atoms with only one mass μ_n , as in the examples considered in this work (crystals of Co, Zr, Ti). In summary, the phase (or Goldstone) and amplitude (or Higgs) oscillations always start from an SSB, but only in some special cases it is possible to associate them with a unique character of the acoustic and optical phonon (Meier et al., 2019; Juraschek et al., 2020).

Conclusion

A recently introduced viewpoint enabled the description of Goldstone and Higgs modes in clearly identifiable structural phase transitions occurring in widely available natural crystalline solids.

Within the Ginzburg–Landau theory formalism, we identified the potential energy term with the crystal free energy difference $F(\phi)$ between a parent, symmetric phase and a product phase with broken symmetry by expanding the total energy of crystal atoms around their equilibrium positions.

Goldstone (phase) and Higgs (amplitude) modes emerge when the initial system symmetry is broken during the phase transition to the *hcp* phase. These modes can be identified with the acoustic and optical phonons in the special case of crystals made of only one atomic species.

This perspective offers an example of what in the Standard Model of particle physics is difficult to achieve, that is, the symmetry restoration. A phase transition to a more symmetric *bcc* or *fcc* phase restores the $U(1)$ symmetry, stabilizes the symmetric vacuum state with $\phi_0 = 0$, and reveals a greater crystal symmetry that was hidden in the *hcp* broken phase.

In the event that an SSB is not observed, the acoustic phonons still exist. It is possible to view them as either Goldstone bosons resulting from the breakdown of translational invariance or gauge bosons that mediate lattice interactions within a non-Abelian gauge theory, a subject to be explored in greater detail in future publications.

Abstract

This chapter discusses three different points at which condensed matter physics makes contact with foundational issues of quantum mechanics: (i) The effects of Fermi and Bose “statistics” in macroscopic systems. (ii) The Aharonov-Bohm effect. (iii) Does quantum-mechanics retain its validity at the everyday level?

Introduction

When one thinks about fundamental tests of the principles of quantum mechanics, the area of condensed matter physics is not the first that springs to mind. At least at first sight, such tests would seem to require the use of physical systems which are very well characterized, well isolated from their environments, and (for certain kinds of tests) propagate at or close to the speed of light. None of these conditions is at all well satisfied by a typical condensed matter system. Nevertheless, there are certain kinds of fundamental tests for which such systems are indispensable and others for which they permit substantial extensions of the results obtained on more “microscopic” systems, and this is the subject of this article. Apart from “quantum statistics,” the issues discussed are: one aspect of nonlocality in quantum mechanics, and the universal validity of the quantum description.

Quantum statistics

It is a well-known consequence of the basic principles of the quantum field theory that “elementary” particles can be partitioned into two and only two classes, based on their possessing integral or half-odd-integral spin in units of $\hbar$; these are called bosons and fermions respectively (cf. below for the names). A very fundamental consequence of the indistinguishability in principle of elementary particles, coupled with considerations peculiar to the relativistic quantum field theory, is the spin-statistics theorem: the wave function of any quantum-mechanical system containing more than one particle must be unchanged under the exchange of any two identical bosons, and must change sign under the exchange of any two identical fermions. (A conventional, if somewhat imprecise, phrasing of this principle is that particles of integral (half-odd-integral) spin obey Bose (Fermi) “statistics.”) The spin-statistics theorem has been well confirmed at the level of particle physics, for example, in the selection rules on decay processes, and in the case of fermions one of its consequences, the Pauli exclusion principle which forbids more than one fermion from occupying any single-particle state, has well-known effects for the structure of both atoms and nuclei. The spin-statistics theorem applies not only to “elementary” particles but also to complexes built up from the latter, provided that (1) the “internal” structure of the composites is identical, and (2) they remain undissociated in the regime of interest. This follows because if S is the total spin of the complex, the parity of $2S$ is just that of the total number of fermions contained in it, and this is also the parity of the wave function under the simultaneous exchange of all the fermions between two such complexes. Thus, for example, the ^4He atom (2 electrons, 2 protons, 2 neutrons, $S = 0$) behaves as a boson, while the ^3He atom (2 electrons, 2 protons, 1 neutron, $S = 1/2$) behaves as a fermion. The same conclusion obviously applies to the even and odd isotopic species of any chemical element. Does this difference in “statistics” have any effect in the macroscopic limit?

Actually, it is an experimental fact that the properties of most substances do not depend qualitatively on their isotopic composition. The reason is that for the effects of the statistics to be appreciable, two conditions must hold simultaneously. The first is that the behavior predicted by a quantum-mechanical calculation should differ appreciably from that obtained in the classical approximation (if this is not true, then the whole concept of a wave function becomes unnecessary, so its symmetry clearly cannot affect any physical property); this requires that the thermal de Broglie wavelength of the particles in question should be greater than, or at least comparable to, the average interparticle spacing. The second condition is that the particles in question can

[☆]Change History: Change History: August 2022. AJ Leggett updated section “Limits on the validity of quantum mechanics.”

exchange places fairly readily; if this is not so, it is easy to show that the symmetry of the wave function under interchange can have no substantial consequences. Now for almost all elements and compounds, at temperatures low enough for the first condition to be satisfied the system is already solid, so that the second condition is violated (in a solid the atoms change places, if at all, only very rarely). In fact, by the traditional definition the only “condensed matter” systems where the two conditions are simultaneously satisfied are the above two stable isotopes of helium, both of which are unique in remaining liquid under their own vapor pressure down to the lowest temperatures investigated.

The effect of the “statistics” on the behavior of liquid helium is indeed spectacular. The two isotopes, ^4He and ^3He , are essentially identical in their electronic structure and interatomic interactions, and the difference in nuclear mass does not seem to have any major qualitative effect; indeed, in the solid phase the properties of the two species are very similar (with the exception, of course, of those associated explicitly with the nuclear spin degree of freedom, which is peculiar to ^3He). Despite this, the properties in the liquid phase are completely different: in the case of liquid ^4He , the liquid enters, below the so-called λ -temperature of ~ 2.17 K, a “superfluid” phase which displays a variety of exotic properties (persistent currents, nonclassical rotational inertia, film creep, fountain effect, etc.). By contrast, liquid ^3He behaves, right down to temperatures below 3 mK, in a way qualitatively similar to that of any other liquid, and in particular, shows none of the above exotic effects. (Below 2.6 mK, liquid ^3He does indeed become superfluid, but as shall be seen below, the character of the superfluid phase(s) is/are rather different from that occurring in ^4He .)

The origin of this spectacular difference in the behavior of the two isotopes (or at least of much of it) may be understood, at least qualitatively, by asking how they would behave in the complete absence of interactions between the atoms. If N identical noninteracting atoms (of either species) are considered to be moving in a volume V , the relevant single-particle energy eigenstates are plane waves of the form

$$\psi_k(r) = V^{-1/2} \exp(ik \cdot r) \quad (1)$$

If the system is considered to be in thermal equilibrium at temperature T and the standard principles of statistical mechanics are applied subject to the constraints imposed on the many-particle wave function by the spin-statistics theorem, one finds that the distribution $n_k(T)$ of atoms between the single-particle plane-wave states (1) is given by the formula

$$n_k(T) = (\exp((\epsilon_k - \mu)/k_B T) \pm 1)^{-1}, \epsilon_k \equiv \hbar^2 k^2 / 2m \quad (2)$$

where the plus sign applies for fermions and the minus sign for bosons. In these formulas, the quantity $\mu(T)$ is the chemical potential, and its value is fixed, for either sign, by the self-consistency condition

$$\sum_k n_k(T; \mu(T)) = N \quad (3)$$

The consequences of the sign difference are profound: for fermions, in the limit $T \rightarrow 0$, the N lowest-energy single-particle states are each occupied by a single atom, in accordance with the Pauli exclusion principle; one can say that they fill up a “Fermi sea” or “Fermi sphere” in momentum space, with a radius k_F given (for spin 1/2) by the formula $k_F = (3\pi^2 n)^{1/3}$, where $n \equiv N/V$. At nonzero but low temperatures, particles can be excited to states which lie $\lesssim k_B T$ in energy above the top of the Fermi sea, leaving “holes” in a similar range in the sea. Although such a “free Fermi gas” model is of course not a realistic picture of real liquid ^3He , it turns out that the modifications necessary to take account of the interatomic interactions do not change the situation qualitatively (this is the essential content of Landau’s “Fermi-liquid” theory), and that the behavior of the resulting system is overall not very different from that of a classical liquid; in particular, it is predicted to show none of the exotic effects seen in liquid ^4He .

In the case of a system of noninteracting bosons, which is described by Eq. (2) with the minus sign, the behavior is again not qualitatively very different from that of a normal liquid so long as the chemical potential μ has a finite negative value (which is the case at sufficiently high temperatures). As the temperature falls, however, the value of $\mu(T)$ increases, and for a system moving in free space there exists a nonzero temperature T_c (whose value depends on the density n) below which such a nonzero negative value of μ is incompatible with the self-consistency relation (3). For $T < T_c$, the chemical potential tends to zero, and a finite fraction of all the atoms (i.e., a macroscopically large number N_0) occupies the lowest-energy single-particle state, namely that with $k = 0$. This is the phenomenon known as Bose–Einstein condensation (BEC). For a gas of atoms with the mass and density of ^4He , the onset temperature T_c of BEC is ~ 3.3 K, not far from the temperature (2.17 K) of the onset of superfluidity in liquid ^4He . It is the almost universal belief that below this latter temperature, BEC indeed occurs in liquid ^4He , and that this is the origin of the complex of exotic properties observed in that system.

To illustrate how BEC can give rise to this kind of exotic behavior, let us focus, for definiteness, on the property of “nonclassical rotational inertia.” Consider a free gas of N identical atoms (of any species) in a toroidal (annular) container of radius R and thickness $d \ll R$, which rotates at an angular velocity $\omega < \omega_c/2$, where $\omega_c \equiv \hbar/mR^2$. What is the angular momentum of the system in thermal equilibrium? Classical intuition suggests that the system would like to rotate so that its mean velocity exactly matches that of the container, and that its angular momentum will then be simply $NmR^2\omega$. It is easy to show that a system which is well described by classical (Newtonian) mechanics will indeed behave in just this way. For a quantum-mechanical system, it turns out that the effect of the rotation is to change the “effective” energy of a single-particle state with angular momentum l from its original energy $l^2 \hbar^2 / 2mR^2$ to $l^2 \hbar^2 / 2mR^2 - \hbar\omega l$. For a system of any species which is not Bose-condensed, the distribution given by formula (2) is a smooth function of energy, and provided only that the thermal energy $k_B T$ is $\gg \hbar^2 / mR^2$ (a condition very well satisfied in any currently realistic experiment), the classical result for the total angular momentum is obtained. However, for a boson system below T_c , a macroscopic fraction of all the atoms must occupy the single lowest-(effective)-energy single-particle state; for $\omega < (1/2)\omega_c$ this

is a state with $l = 0$, so a fraction of the atoms stays at rest in the laboratory frame and the observed angular momentum is less than the classical value. Again, this simple model is not a realistic description of liquid ^4He (and in fact, cannot account for all the exotic behavior of the latter), but a model which takes adequate account of the interatomic interactions while still assuming the existence of BEC has been very successful in explaining all the main phenomena of superfluidity in that system.

Finally, it is generally believed that below 2.6 mK the fermions in liquid ^3He form “Cooper pairs”—a sort of giant “diatomic molecules.” (A similar phenomenon occurs for the electrons in metals below the transition temperature for superconductivity, but the Cooper pairs in ^3He have a more sophisticated structure). Since such pairs of fermions have integral spin, they are in effect bosons and can (and do) undergo Bose condensation. One, therefore, expects the system to show exotic properties such as those displayed by ^4He below the λ -temperature, and indeed such are found.

Thus, the two isotopes of liquid helium manifest, in a dramatic way, the consequences of a fundamental principle, the indistinguishability, in principle, of elementary particles.

Aharonov–Bohm effect

In the classical electromagnetic theory, all electromagnetic effects on charged particles can be obtained from a knowledge of the electric and magnetic fields “seen” by the particle, that is, the fields at the position of the latter; the electromagnetic vector potential $A(\mathbf{r}, t)$ is introduced purely as an auxiliary function to simplify some of the calculations. However, in quantum mechanics the situation is different. Consider an experimental arrangement in which a solenoid, regarded here as of infinite length, carries a finite steady current (see Fig. 1). The magnetic field produced by the current is entirely confined to the interior of the solenoid; outside it is zero. Now consider a beam of electrons which is split so as to pass on either side of the solenoid, and detected on a screen behind it (Fig. 1). According to a quantum-mechanical calculation, the position of the interference fringes observed on the screen should depend on the current in the solenoid, being periodic in the flux through the latter with period h/e . This is despite the fact that there are no electric or magnetic fields at any point on the trajectories of the electrons! This strange behavior, usually known as the Aharonov–Bohm effect, can be interpreted as showing either that the electrons can “feel” fields even at points they never travel to, or that the vector potential has a “physical reality” not envisaged in the classical electromagnetic theory.

While the most loophole-free tests of the Aharonov–Bohm effect have been done with electron beams in free space, the use of condensed-matter systems permits one to display the effects of this “nonlocality” on a macroscopic scale. This is possible in a superconductor, since, to produce the superconducting state, the electrons must form Cooper pairs (as in the superfluid phase of liquid ^3He , see above), and these pairs then effectively form bosons and undergo a sort of BEC (again just as in ^3He). Suppose now one forms the completely superconducting device shown in Fig. 2; in the present context it is enough to know that each junction by itself can carry, without dissipation, a certain maximum (“critical”) current I_c , which is assumed for simplicity to be the same for the two junctions. Thus, if one of the arms were blocked the critical current of the device would simply be I_c while if both are open and there is no current in the solenoid S , the currents in the two arms just add and the critical current of the device is $2I_c$. If however, one imposes a current through the solenoid and thus generates a total flux ϕ through the device, it turns out that the critical current of the latter should be modulated by a factor $|\cos(\pi\phi/\phi_0)|$; thus it is periodic in the (superconducting) “flux quantum” $\phi_0 \equiv h/2e$. (The reason the period is $h/2e$ rather than h/e as in the electron beam case is that the Cooper pairs have charge $2e$, not e .) As in the electron-beam case, this is despite the fact that the electrons which carry this current never experience any electric or magnetic fields. This prediction is well verified experimentally, showing that the Aharonov–Bohm effect has not merely atomic-level but also macroscopic manifestations.

Fig. 1 The Aharonov–Bohm effect. The magnetic field of the solenoid is confined to its interior, so there are no fields at any point on the paths taken by the electrons.

Fig. 2 The Aharonov–Bohm effect in a superconducting circuit. The solenoid produces no field anywhere in the metal.

Limits on the validity of quantum mechanics

The quantum measurement paradox (or, as it is sometimes known after its most famous instantiation, the “Schrödinger’s Cat” paradox) may be stated succinctly as follows: at the microscopic level, if one considers a standard example such as the Young’s slits experiment with attenuated beams of single electrons, the fact that the probability amplitude (wave function) which in quantum mechanics describes the ensemble in question, has a finite value at each of the two slits of the intermediate screen cannot, at least without extreme contortions, be interpreted as implying that each individual electron of the ensemble passed through a definite slit (so that the only significance of the amplitude is that its square is a measure of the probability of a given electron passing through the slit in question). The evidence for the above statement is the phenomenon of interference at the final screen. Now, if one believes (as most physicists do) that quantum mechanics is, in principle, the complete truth about the physical universe, it can be applied not just to single electrons and atoms, but to arbitrarily complex objects composed of them, and in this process the formalism itself is in no way modified. This means that it is perfectly possible to devise thought-experiments (such as Schrödinger’s original example involving the cat) such that the unambiguous description given by quantum mechanics of the final state of the universe (or more precisely the relevant “ensemble of universes”) is a linear superposition of amplitudes corresponding to macroscopically distinct outcomes (e.g., living or dead cat). Thus, unless the interpretation of the quantum formalism is changed significantly between the microscopic and macroscopic levels, one is forced to conclude that it is not true that, for example, each individual cat was either alive or dead before inspection. Yet it is (or at least appears to be!) a fact of our direct experience that inspection reveals each cat to be in one state or the other!

In the literature it is often claimed that the apparent paradox can be resolved by appealing to the phenomenon known as “decoherence”: when an object is sufficiently macroscopic, and/or interacts with a sufficiently complex environment, then one effect of this interaction is, in effect, to “scramble” the relative phases of the amplitudes representing the two macroscopically distinct states, so that the reduced density matrix of the system becomes equivalent to that of a classical “mixture” of the two states (which *inter alia* gives no possibility of interference), and can thus (it is claimed) be interpreted as simply saying that one or other of the two states is definitely realized for each cat, but one does not know which, and thus have to give a probabilistic description. While the occurrence and ubiquity of the decoherence phenomenon at the macroscopic level is not in serious dispute, the validity of the last, crucial step in the argument (which is equivalent to a major change in the interpretation of the quantum formalism between the micro- and macro-levels) is controversial in the extreme, so that it is by no means universally agreed in the physics community that the measurement paradox is “solved.”

The premise underlying the above discussion is that since the pristine quantum formalism describes, apparently perfectly, the behavior of individual atoms and molecules, it must likewise describe perfectly, at least in principle, the behavior of arbitrarily complex objects composed of them. Given the situation just described concerning the measurement paradox, it would appear to make sense to ask if one is sure that this premise is actually true, or could it perhaps be that by the time one gets from the level of atoms to that of cats, some new physics comes into play which, *inter alia*, has the effect of reducing any superposition of macroscopically distinct states, not to a mixture as the “decoherence” argument would have it, but to a definite one of its branches for any given system of the ensemble? The class of theories which have these properties are termed “macrorealistic”; a number of such theories have appeared in literature, the most fully developed probably being that associated with the names of Ghirardi, Rimini, Weber, and Pearle. The question is whether one could actually devise an experimental test of the class of macrorealistic theories against quantum mechanics.

It is fairly obvious that to the extent that a superposition of macroscopically distinct states is *ipso facto* automatically subject to a degree of decoherence sufficient to reduce the density matrix to that of a classical mixture, it will be impossible to implement such a test, because the experimental predictions of the “mixture” description are, by definition, equivalent to those of a theory in which a definite outcome is realized for each system, that is, a macrorealistic theory. The experimental challenge is thus to find a system where the superposition is both of “macroscopically distinct” states and at the same time sufficiently resistant to decoherence. Of course, the possibility of doing so rests on the definition of “macroscopically distinct,” and this point has had considerable discussion in literature; for present purposes, it is adequate to define two states as having this property relative to one another if there is at least one extensive physical quantity whose expectation value in the two states is different by some large number (say 10^4 – 10^9 , see below) in the “natural” (atomic) units. Below, for convenience, this number is denoted by the symbol Λ .

Suppose, for the sake of argument, that one has found such a system; then one can try to engineer a situation where, if quantum mechanics is indeed the whole story, at some stage the correct description of the relevant ensemble is indeed a linear superposition of two (or more) macroscopically distinct states. At that point one can, in principle, (1) test whether the predictions of quantum mechanics in fact correspond to experiment, and (2) test whether predictions made on the basis of a macrorealistic theory correspond to experiment. While it can be shown that there exist experimental situations in which a positive answer to (1) automatically implies a negative answer to (2) (i.e., confirmation of the quantum-mechanical predictions automatically refutes the whole class of macrorealistic theories), such experiments have been realized only quite recently, and the experiments to be described in the next paragraph have been of type (1) only. In such tests, the interpretation of the raw data is always done in explicitly quantum-mechanical terms, and the question being asked is whether the experimentally realized state is, as predicted by theory, a superposition or rather a mixture of macroscopically distinct states.

Condensed matter experiments which were consciously designed to test the validity of quantum mechanics at the macroscopic level were started as early as 1980. The first generation of these experiments looked for, and saw, the essentially quantum-mechanical phenomenon of tunneling out of a metastable well (often referred to, in this context, as “macroscopic quantum tunneling” or MQT). A second generation of experiments has looked more directly for the effects of superposition, by testing for NH_3 -type oscillations or a related phenomenon. The system of choice is usually a bulk superconducting ring interrupted by a single Josephson junction (“flux qubit”), or some variant thereof, and the two states in question are states in which the current circulates clockwise or counterclockwise respectively; depending on the details of the geometry, the value of Λ can range from 10^4 to 10^9 . If such a system is subjected to an external flux Φ_{ext} , the energy eigenstates are (in the absence of decoherence) linear superpositions of the above two states; for the special case $\phi_{\text{ext}} = \phi_0/2 = h/4e$, the ground state has even parity and the excited state odd parity, and the level splitting is twice the matrix element t for tunneling between the clockwise- and anticlockwise-circulating states. More generally, as a function of flux the level splitting has the form

$$\Delta E = 2\sqrt{t^2 + \text{const.}(\phi - \phi_0/2)^2} \quad (4)$$

as shown by the solid lines in Fig. 3. By contrast, if the true density matrix of the system is a mixture then the splitting should be linear in the flux, as indicated by the broken lines. In the experiments (which used a spectroscopic technique to measure the splitting), it was unambiguously the solid line which was found.

In one set of experiments, the value of Λ was $\sim 10^9$, which is probably a record at the time of writing. Note however that these experiments, while verifying that the behavior at this level is consistent with the predictions of quantum mechanics, have not explicitly excluded theories of the macrorealistic class.

Fig. 3 The predicted dependence of the energies of the two lowest states of an RF SQUID ring on the externally applied flux, under the assumption of a coherent superposition (solid lines) or a mixture (broken lines).

In 2016 the NTT group in Japan [Knee \(2016\)](#) reported the first definitive experiment of type (2). This was essentially a simple “Young’s slits” experiment in which the “slits” were two states of a flux qubit which were, at least arguably, macroscopically distinct (see supplementary note 3 of Knee et al.), and in which the raw data was the dependence of the post-slit behavior on whether or not an observation was made on which “slit” was traversed. The results are in agreement, within the error bars, with the predictions of quantum mechanics, and violate those of any macrorealistic theory by more than 80 standard deviations. Thus it seems that the idea of macrorealism is untenable at least at the level of flux qubits. Whether it may become viable at a level closer to that of direct human experience is a matter for further experiments in the future.

Abstract

We briefly review the theoretical formulations and applications of the Aharonov–Bohm effect and the Aharonov–Casher effect in condensed physics with emphasis on mesoscopic physics. Topics relating to the Aharonov–Bohm effect include locality, periodicity, nonintegrable phase factors, Abelian gauge theory, interference, the spectrum and persistent current of electrons on a ring pierced by a magnetic field, Onsager reciprocity relations, and Aharonov–Bohm interferometer. Topics relating to the Aharonov–Casher effect include a magnetic dipole in an electric field, locality, periodicity, non-Abelian gauge invariance, $SU(2)$ nonintegrable phase factors, spin–orbit coupling, Pauli equation, Rashba Hamiltonian, Aharonov–Casher interferometer, conductance and polarization in two-channel systems due to the Aharonov–Casher effect. We also touch upon Aharonov–Bohm effect in cold atom physics and the topic of magnetic monopoles.

Introduction

The Aharonov–Bohm effect (Aharonov and Bohm, 1959) and Aharonov–Casher effect (Aharonov and Casher, 1984) are purely quantum mechanical in nature. They highlight the crucial role of the phase of the wave function and its experimental significance (Berry, 1984; Loss et al., 1990; Stern et al., 1990; Stern, 1992; Aronov and Lyanda-Geller, 1993; Qian and Su, 1994). The Aharonov–Bohm effect shows that a charged particle is affected by a magnetic field even if the particle is confined to a region in which the magnetic field $\mathbf{B}$ is absent. Thus, the magnetic field acts nonlocally on charged particles, and the fundamental pertinent field affecting charged particle is the vector potential $\mathbf{A}$, and the relevant theory is characterized by Abelian gauge invariance.

The Aharonov–Casher effect applies to particles with an intrinsic magnetic moment (they need not necessarily be charged), whose (spinor) wave function acquires a matrix-valued phase factor. Consequently, the relevant theory is characterized by non-Abelian gauge invariance (Yang and Mills, 1954).

Several examples relevant to condensed matter physics are discussed, mainly for mesoscopic systems (Stone, 1985; Lee and Stone, 1985; Imry, 1997; Akkermans and Montambaux, 2007), supported by short derivations of the basic equations that model the observed phenomena.

Aharonov–Bohm effect

The Aharonov–Bohm effect (Aharonov and Bohm, 1959, 1961; Aharonov and Anandan, 1987) is a spectacular manifestation of the difference between classical and quantum theories of charged particles interacting with electromagnetic forces; it stresses the crucial role of the phase of the charged particle’s wave function. It predicts that the behavior of a charged particle is affected by the electromagnetic field even when the particle is always in a region where the field vanishes. Shortly after being predicted, it was first confirmed experimentally (Chambers, 1960). An experimental verification in a toroidal magnetic field was reported in Osakabe (1986) and its verification in carbon nano tubes was reported in Bachtold et al. (1999). It was also confirmed in tunneling experiments (Noguchi et al., 2014) and tomography (Valagiannopoulos et al., 2018).

In classical electrodynamics, the electric and magnetic fields $\mathbf{E}$ and $\mathbf{B}$ fully describe the electromagnetic field and the phenomena involving the interaction of matter and photons. The vector potential $\mathbf{A}$ is introduced as an auxiliary field in order to solve Maxwell’s equations (see however Vaidman, 2011). In quantum mechanics, the Aharonov–Bohm effect shows that this is not the case. For charged particles, knowing $\mathbf{B}$ (assume $\mathbf{E} = 0$ for simplicity) does not completely determine all the electromagnetic effects on the particle. Experimental and theoretical consequences of the Aharonov–Bohm effect were elaborated in numerous papers and books, see for example Olariu and Popescu (1985), Peshkin and Tonomura (1989), and Tonomura (2006).

In order to describe the effect in simple terms, let us consider, as in Fig. 1 (Shech, 2022), a two-slit interference pattern of electrons moving in the x - y plane. The plane is pierced by a circular tube of radius R centered at the origin, namely $\sqrt{x^2 + y^2} < R$, in which there is a uniform perpendicular magnetic field, $\mathbf{B} = B_z \Theta(R - r)$ (see the small circle with B in Fig. 1). Outside the tube $\mathbf{B} = 0$ yet $\mathbf{A} \neq 0$ (but nevertheless, the magnetic field $\nabla \times \mathbf{A} = 0$), see Tonomura (2006) and Batelaan and Tonomura (2009). The electron wave function is $\psi(\mathbf{r})$ and the density pattern on the screen on the right is proportional to $|\psi(\mathbf{r})|^2$. The line integral $\oint \mathbf{A} \cdot d\mathbf{r} = \pi R^2 B \neq 0$ along any closed curve encircling the tube equals the magnetic flux through the tube. Because of the Aharonov–Bohm effect, experiments performed on electrons that are located outside the flux tube (where $\mathbf{B} = 0$), for example, measuring the density on the screen), yield results that depends solely on the (dimensionless) quantity

$$\Phi_{AB} \equiv \frac{e}{\hbar c} \oint \mathbf{A} \cdot d\mathbf{r} \neq 0. \quad (1)$$

This quantity is called the Aharonov–Bohm phase. In a sense, the magnetic field acts where it is not present (see however Avishai et al. 1972; Roy 1980; Vaidman 2008; Popescu 2010; Vaidman 2012; Pearle and Rizzi 2017; Heras 2022). In other words, knowledge of the scalar potential V and the vector potential $\mathbf{A}$ contain more information than the information about the fields $\mathbf{E}$ and $\mathbf{B}$. The Aharonov–Bohm effect can also test the role of the gravitational potential versus that of the gravitational field (Dowker, 1967; Hohensee et al., 2012; Overstreet et al., 2022).

Fig. 1 Aharonov–Bohm interference experiment (schematic): A coherent electron beam emanating from the source propagates in a region where there is no magnetic field but is affected by a flux tube of radius R (with the electron beam not able to enter the tube) within which the magnetic field $\mathbf{B}$ (along the axis of the tube) is finite and uniform; hence, the magnetic flux is $\Phi_{AB} = \pi R^2 B$. The interference pattern on the screen is a periodic function of Φ_{AB} with period $\frac{\hbar c}{e}$. The original pattern (bold line) is obtained for $\Phi_{AB} = n\Phi_0$ and the shifted pattern (dashed line) is obtained for $\Phi_{AB} \neq n\Phi_0$ ($n = \text{integer}$). Modified from Shech E (2022) Scientific understanding in the Aharonov–Bohm effect. Theoria 88: 943, Fig. 2

Periodicity in the Aharonov–Bohm phase

As predicted by Aharonov and Bohm and substantiated shortly after their publication (Byers and Yang, 1961), such experimental results are periodic functions of Φ_{AB} with period

$$\Phi_0 \equiv \frac{hc}{e} = 4.1414 \times 10^{-7} \text{ Gauss} \cdot \text{cm}^2, \quad (2)$$

which serves as a quantum unit of flux. Consequently, Wu and Yang (1975) introduced the concept of *phase factor*,

$$\Lambda_{AB} \equiv e^{i\Phi_{AB}}, \quad (3)$$

and stressed that, although Φ_{AB} contains more information than Λ_{AB} , this extra information is not measurable. In other words, the result of experiments depend solely on the phase factor Λ_{AB} . If there are two cases a and b such that $\Phi_{AB}^a - \Phi_{AB}^b = n \frac{hc}{e}$ ($n = \text{integer}$), no experiment performed on an electron *outside the tube* can distinguish between the two cases.

Gauge invariance

The proof of the statement above (Wu and Yang, 1975) proceeds by applying a (unitary) *gauge transformation* between the corresponding electron wave functions, $\psi_b(\mathbf{r}) = e^{i\alpha(\mathbf{r})}\psi_a(\mathbf{r}) \equiv S(\mathbf{r})\psi_a(\mathbf{r})$, implying $\mathbf{A}_b(\mathbf{r}) - \mathbf{A}_a(\mathbf{r}) = \frac{hc}{e} \nabla \alpha(\mathbf{r})$. Since the curl of the left-hand side vanishes, the solution for $\alpha(\mathbf{r})$ is $\alpha(\mathbf{r}) = \frac{e}{hc} \int_{\mathbf{r}_0}^{\mathbf{r}} [\mathbf{A}_b(\mathbf{r}) - \mathbf{A}_a(\mathbf{r})] \cdot d\mathbf{r}$, where $\mathbf{r}$ and $\mathbf{r}_0$ are two points along the chosen curve outside the tube. Therefore,

$$\frac{e}{hc} \oint [\mathbf{A}_b(\mathbf{r}) - \mathbf{A}_a(\mathbf{r})] \cdot d\mathbf{r} = \Phi_{AB}^b - \Phi_{AB}^a = 2n\pi, \quad (4)$$

hence, $[\Lambda_{AB}]_a = [\Lambda_{AB}]_b$. In the language of Wu and Yang (1975), *the two cases are gauge transformable into each other and no physically observable effects can differentiate between them*.

The concept of gauge transformation is generalized to the case where the line integral is performed for any curve between $\mathbf{r}_0$ and $\mathbf{r}$ by introducing a *nonintegrable (path dependent) phase factor*,

$$\Lambda_{pq} \equiv e^{\frac{ie}{hc} \int_{\mathbf{r}_p}^{\mathbf{r}_q} \mathbf{A}(\mathbf{r}) \cdot d\mathbf{r}}, \quad (5)$$

such that an arbitrary gauge transformation $e^{\frac{ie}{hc} f(\mathbf{r}_p)} \Lambda_{pq} e^{-\frac{ie}{hc} f(\mathbf{r}_q)}$ does not affect the result of measurements. Here $f(\bullet)$ is any continuous function taking $\mathbf{r}_p$ outside the tube to $\mathbf{r}_q$ outside the tube, and the factor $e^{\frac{ie}{hc} f(\mathbf{r})}$ is a transformation of the wave function $\psi(\mathbf{r})$. Wu and Yang then conclude that *electromagnetism is the gauge-invariant manifestation of nonintegrable phase factors*.

Examples in condensed matter physics

In the Aharonov–Bohm effect, phase coherence is a crucial factor. Hence, pertinent experiments must be carried out at low temperature and with systems of small size (up to a few microns). The underlying physics of systems whose size is larger than the atomic size but much smaller than macroscopic size is termed *mesoscopic physics* (Lee and Stone, 1985; Stone, 1985; Imry, 1997; Akkermans and Montambaux, 2007). In the examples discussed below, the spin of the electron does not play a role. The Aharonov–Bohm effect for particles with spin is discussed in Hagen (1990), Nitta et al. (1997), Morpurgo et al. (1998), Nitta et al. (1999), Yau et al. (2002), and Grbic et al. (2007).

Interference

Fig. 1 is a schematic description of an Aharonov–Bohm interference wherein a beam of electrons propagates toward a screen. The electrons avoid the tube through which a magnetic field generates a magnetic flux Φ_{AB} . Outside the tube the magnetic field vanishes but the vector potential $\mathbf{A}$ is finite. The electrons do not feel the magnetic field, but on going outside the tube from a point q to a point p the wave function of the electron gains a phase as given in Eq. (5). This leads to an interference pattern whose intensity is shown on the screen. The intensity pattern is periodic in Φ_{AB} with period $\Phi_0 = \frac{hc}{e}$.

Electrons on a ring

Impressive progress in experimental techniques has enabled fabrication of micron-sized conducting rings (Webb et al., 1985; Imry and Webb, 1986). Specifically, consider uniformly distributed electrons propagating in a small metallic ring of radius R and length $L = 2\pi R$. The ring is placed on a plane and pierced by a perpendicular magnetic field $\mathbf{B}$ such that the magnetic flux is $\Phi_{AB} = \pi R^2 B$, and the corresponding vector potential $\mathbf{A} = \frac{\Phi_{AB}}{L} \hat{\boldsymbol{\theta}}$ is along the ring (the magnetic field acting on the circumference of the ring vanishes). Here the electrons are treated as noninteracting spin less fermions of charge $-e$ and mass m (see however, Hagen (1990)). Due to the Aharonov–Bohm effect, this simple system exhibits beautiful phenomena both in equilibrium and, if coupled to leads with a small potential difference, out of equilibrium (see the Section Aharonov–Bohm interferometer below).

Spectrum

Let $0 \leq x \leq L$ denote an electron coordinate along the ring. The time-independent Schrödinger equation for electrons (charge $-e$ and mass m_e) moving on the ring is,

$$H\psi = \frac{1}{2m_e} \left(p + \frac{e}{c} \frac{\Phi_{AB}}{L} \right)^2 \psi = \varepsilon \psi, \quad (6)$$

where $p = -i\hbar \frac{d}{dx}$ is the momentum operator and c is the speed of light. Note that $[p, H] = 0$ since Φ_{AB} is independent of x . The periodic solutions are plane waves, $\psi(x) = L^{-1/2} e^{ikx}$. Since the wave function must be single valued, the wave numbers are quantized, $k = k_n = 2n\pi/L = n/R$, with $n = 0, \pm 1, \pm 2 \dots$. Substituting this wave function into Eq. (6), one obtains the energy eigenvalues E_n ,

$$\begin{aligned} \varepsilon_n(\Phi_{AB}) &= \frac{1}{2m_e} \left(\hbar k_n + \frac{e\Phi_{AB}}{cL} \right)^2 \\ &= \frac{\hbar^2}{2m_e R^2} \left(n + \frac{\Phi_{AB}}{\Phi_0} \right)^2, \end{aligned} \quad (7)$$

Note that $\varepsilon_n(\Phi_{AB})$ is not periodic in Φ_{AB} and also, $\varepsilon_n(\Phi_{AB}) \neq \varepsilon_n(-\Phi_{AB})$ (which is physically wrong). Using the degeneracy $\varepsilon_{n+1}(\Phi_{AB}) = \varepsilon_n(\Phi_{AB} + \Phi_0)$ we can reorder the quantum numbers $\{n \in \mathbb{Z}\}$ and the energies $\{\varepsilon_n(\Phi_{AB})\}$ such that (see Fig. 2),

$$0 \leq E_n(\Phi_{AB}) \leq E_{n+1}(\Phi_{AB}), \quad (8)$$

$$E_n(\Phi_{AB}) = E_n(\Phi_{AB} \pm m\Phi_0) = E_n(-\Phi_{AB}), \quad (9)$$

where $n, m = 0, 1, 2 \dots$

At zero temperature, the ground-state energy is given by the sum of single-particle energies of levels below the Fermi energy E_F ,

$$E_{\text{gs}}(\Phi_{AB}) = 2 \sum_{E_n(\Phi_{AB}) < E_F} E_n(\Phi_{AB}). \quad (10)$$

where the factor 2 is due to spin degeneracy. At higher temperature, the levels are occupied according to the Fermi-Dirac distribution function.

Persistent current

One of the important consequences of the Aharonov–Bohm effect in the ring geometry is that there can exist a nonzero steady-state current in the ring. This was first suggested in Büttiker et al. (1983), and was observed experimentally several years later (Schwarzschild, 1986; Levy et al., 1990). The existence of the current is related to the fact that in a magnetic field, time-reversal symmetry is violated and the Hamiltonian is complex (albeit Hermitian). This current is not the usual conduction current where electrons in a metal at the Fermi energy exchange energy with an external electric field. Rather, it is an equilibrium property of the system, and there is no dissipation associated with this current. For the moment, confining our discussion to zero temperature, all the electrons in the levels below the Fermi energy E_F contribute to the current. The current operator can be written as

$$\hat{I} = -c \frac{\partial H}{\partial \Phi_{AB}} = \frac{-e}{L} \left[\frac{1}{m} \left(p + \frac{e\Phi_{AB}}{cL} \right) \right] = \frac{-e}{L} \hat{v}, \quad (11)$$

where $\hat{v}$ is the velocity operator. The contribution of level n below the Fermi energy to the current is obtained by taking the expectation value of $\hat{I}$ with the wave function ψ_n . Using the Feynman-Hellman theorem, we can equate the expectation $\langle \psi_n | \frac{\partial H}{\partial \Phi_{AB}} | \psi_n \rangle$ to $\frac{\partial E_n(\Phi_{AB})}{\partial \Phi_{AB}}$. The total current at zero temperature is then given by

$$I(\Phi_{AB}) = -c \sum_{E_n(\Phi_{AB}) < E_F} \frac{\partial E_n(\Phi_{AB})}{\partial \Phi_{AB}} = -c \frac{dE_{\text{gs}}}{d\Phi_{AB}}. \quad (12)$$

Fig. 2 Energy eigenvalues $E_n(\Phi_{AB})$ versus magnetic flux Φ_{AB}/Φ_0 . Level crossings occur at $\Phi_{AB} = m\Phi_0$ and $\Phi_{AB} = (m + 1/2)\Phi_0$ in a clean system (m =integer). However, any amount of disorder or imperfection leads to avoided crossings and a pattern of energy bands with small gaps between them. For any fixed value of the flux, the levels should be ordered from low energy to higher energy. The ground-state energy of a single electron is shown as the thick red line. With this ordering, the spectrum is a periodic function of the flux with period Φ_0 . Taken from Band Y and Avishai Y (2012) Quantum Mechanics with Application to Nanotechnology and Information Science, Elsevier.

As a result of the properties of the spectrum listed above, it is clear that the current is a periodic function of Φ_{AB} with period Φ_0 and is an antisymmetric function of the flux

$$I(\Phi_{AB}) = -I(-\Phi_{AB}), \quad I(\Phi_{AB} + m\Phi_0) = I(\Phi_{AB}). \quad (13)$$

The above analysis is pertinent to a one-dimensional metallic ring geometry. It is worthwhile mentioning other geometries. Persistent current is analyzed for a Corbino disk geometry (Avishai et al., 1993; Avishai and Kohmoto, 1993; Yerin et al., 2021), and for a closed flux line of arbitrary shape and size (Heras, 2022). The Aharonov–Bohm effect for an electron on a spherical shell was discussed by Wu and Yang (1975).

What happens if the ring is not “clean,” for example, if a disordered potential is present in the ring? (Altshuler et al., 1981; Imry, 1997). In this case, the electrons can be scattered elastically from numerous fixed scattering centers. Such scattering centers are related to imperfections and impurities. Experimentally, they are often unavoidable. In many cases, the positions and potential strengths of these impurities are generically random; this kind of potential is called *quenched disorder*. The main consequences of the presence of quenched disorder in the ring are as follows:

1. Level crossings shown in Fig. 2 are avoided and the dependence of energy levels on the flux is smooth.
2. The periodicity and symmetry relations of the energy and current remain unchanged. The Fourier expansion of the current is

$$I = \sum_{k=1}^{\infty} I_k \sin(2\pi k \Phi_{AB} / \Phi_0). \quad (14)$$

In some experiments, the current is found to have an effective period of $\Phi_0/2$ because, in the presence of weak disorder, the dominant Fourier components have even k (Imry, 1997).

3. In the presence of quenched disorder, the wave functions in one dimension decay exponentially at long distance with some characteristic length scale ξ which depends on energy and strength of disorder, and referred to as the *localization length*. This phenomena is termed as *Anderson localization* (Anderson 1958). Thus, if the ring size is such that $L > \xi$, we expect the current to decay exponentially with L .
4. For $L < \xi$, the current persists and is measurable.
5. The order of magnitude of persistent current in the presence of quenched disorder depends on the experimental situation. There are experiments on a single ring and then one speaks of a *sample-specific* persistent current. In this case the order of magnitude is E_c/Φ_0 , where according to the Thouless relation, $E_c = \hbar D/\ell^2$ (Edwards and Thouless 1972; Altland et al. 1996), where D is the diffusion constant and ℓ is a typical random walk step.

On the other hand, experiments involving hundreds of rings are referred to as *impurity-ensemble* experiments. The contribution of many currents tends to cancel out since it has, for example, a random slope at the origin ($\Phi_{AB} = 0$). Thus, ensemble averaging is expected to reduce the magnitude of the persistent currents. Calculations pertaining to weak disorder performed at finite temperature within the grand canonical ensemble (Entin-Wohlman and Gefen, 1989) conclude that after sample averaging, the persistent current virtually vanishes. “Grand canonical” means in this connection that the rings are taken to be connected to a particle bath at temperature T , having a chemical potential μ , and the electron number N may change with Φ_{AB} in each ring.

An important aspect of the behavior of such systems is how the interaction between electrons affects the persistent current. Numerical calculations (Berkovits and Avishai, 1995, 1996) reveal significant interaction-induced enhancement of persistent currents in 2D disordered cylinders. In the paper by Entin-Wohlman et al. (2003), it is shown that persistent currents in interacting Aharonov–Bohm interferometers are enhanced by acoustic radiation. See also Zvyagin (2020).

Aharonov–Bohm interferometer

Electron-based interferometry is a powerful method for probing coherent quantum phenomena in condensed matter physics. An example of the relevance of the Aharonov–Bohm effect in a nonequilibrium situation is an electron interferometer, which is experimentally easier to control than an isolated ring. The measured quantities are conductance and current, which are easier to measure than the persistent current. The underlying tool used to calculate these observables is quantum scattering theory. The Aharonov–Bohm interferometer highlights some fundamental concepts in quantum mechanics such as interference, coherence (Imry, 1995), gauge invariance, current conservation, and Onsager reciprocity relations (Onsager, 1931).

In its simplest version, an Aharonov–Bohm interferometer (see Fig. 3) consists of two one-dimensional ideal conductors L and R (for left and right) connected by three port contacts S_L and S_R , sometimes referred to as *splitters*, to an ideal ring-shaped conductor of radius ρ threaded by a central magnetic flux. The conductors are connected on their other side to electron reservoirs at potentials $V_L \approx V_R$ so there is a small potential difference between the left and right reservoirs, and a small current from left to right. There is a single incoming channel and a single outgoing channel, and therefore, according to the Landauer formula (Landauer, 1957; Büttiker et al., 1985), the conductance of the interferometer (in units of the quantum conductance $G_0 \equiv e^2/h$) is equal to the transmission coefficient. The magnetic field vanishes everywhere except at the small aperture marked as black circle. The electrons stay on the wires of the interferometer and do not reach the region where the magnetic field is present. Nevertheless, the transmission (and hence the conductance) depends on the magnetic flux. This is a purely quantum mechanical effect with no classical analog.

To describe the underlying physics, it is useful to introduce dimensionless variables using the radius ρ of the ring as the unit of length. The dimensionless coordinate is x (in units of ρ), the wave number is k (in units of $1/\rho$), the dimensionless energy is

Fig. 3 Schematic illustration of scattering through an Aharonov–Bohm interferometer. Modified from Imry Y (1997) *Introduction to Mesoscopic Physics*. Oxford University Press. page 110 Fig. 5.4

$\varepsilon = \frac{2mE\hbar^2}{\hbar^2} = k^2$ (where E is the energy in physical units), and the dimensionless magnetic flux is $\phi = \Phi_{AB}/\Phi_0$, where $\Phi_0 \equiv \frac{hc}{e}$. The incoming plane wave with (dimensionless) energy $\varepsilon = k^2$ propagates toward the interferometer from the left and is partially reflected at S_L leftward with reflection amplitude r and partially transmitted into the two arms of the ring. After traveling through the two arms of the ring, it is partially transmitted at S_R with transmission amplitude t at partially reflected back to the arms of the ring. The goal is to calculate the transmission and hence, according to the Landauer formula (Landauer, 1957), the conductance $G(k, \Phi_{AB}) = 2 \frac{e^2}{h} |t|^2$. The external flux is a convenient control parameter, and the dependence of $G(k, \Phi_{AB})$ on energy and magnetic flux reflects the roles of quantum interference (at the splitters) and gauge invariance (the periodicity of $G(k, \Phi_{AB})$). Note that the system cannot be regarded as purely one dimensional since part of it (the ring with the flux) is not simply connected. The calculation requires finding the two linearly independent solutions on every 1D arm of the ring and matching the solutions at the two splitters. The motion of the electron on the ring is governed by the Schrödinger equation in the presence of magnetic flux. The variable x in Fig. 3 assumes values $-\infty < x \leq 0$ on L , $0 \leq x < \infty$ on R and $0 \leq x \leq \pi$ on either arm of the ring where $x = 0$ at S_L . Gauge invariance requires that all measurable quantities are periodic functions of ϕ with period 1, and Onsager reciprocity relations require that the conductance is symmetric with respect to ϕ (see Eq. (19)). Thus, we have

$$-\frac{d^2}{dx^2} \psi(x) = k^2 \psi(x), \quad (x < S_L, \quad x > S_R), \quad (15a)$$

$$\left(-i \frac{d}{dx} + \phi\right)^2 \psi(x) = k^2 \psi(x), \quad (S_L \leq x \leq S_R). \quad (15b)$$

The solutions corresponding to an incoming wave from the left (see Fig. 3) are

$$\psi(x) = e^{ikx} + r e^{-ikx} \quad (x < S_L), \quad (16a)$$

$$\psi(x) = t e^{-ikx} \quad (x > S_R), \quad (16b)$$

$$\psi(x) = a e^{i(k-\phi)x} + b e^{-i(k+\phi)x} \quad (S_L \leq x \leq S_R, \text{ upper arm}), \quad (16c)$$

$$\psi(x) = c e^{i(k+\phi)x} + d e^{-i(k-\phi)x} \quad (S_L \leq x \leq S_R, \text{ lower arm}). \quad (16d)$$

The junctions at points S_L and S_R are referred to as splitters. The precise relations between the incoming and outgoing amplitudes at each splitter depend on the detailed structure of the device. The only restriction is that current should be conserved at each splitter. To satisfy this restriction, we characterize the splitters S_L and S_R by two unitary 3×3 S matrices S_L and S_R relating the three amplitudes of the incoming waves in the junction to the three amplitudes of the outgoing waves at this junction. The form of these S matrices is dictated by the requirements of wave function continuity and current conservation but otherwise they are dependent on the structure of the contacts and the experimental setup. Continuity and current conservation at the two junctions yields

$$S_L \begin{pmatrix} 1 \\ b \\ d \end{pmatrix} = \begin{pmatrix} r \\ a \\ c \end{pmatrix}, \quad S_R \begin{pmatrix} 0 \\ a e^{i(k-\phi)\pi} \\ c e^{i(k+\phi)\pi} \end{pmatrix} = \begin{pmatrix} t \\ b e^{-i(k+\phi)\pi} \\ d e^{-i(k-\phi)\pi} \end{pmatrix}. \quad (17)$$

These are six linear inhomogeneous equations for the six unknowns a, b, c, d, r , and t , which can be solved once the unitary matrices S_L and S_R are given. The solution must satisfy continuity of the wave function at the junction and obey the current conservation constraint (Kirchhoff's law). These constraints determine the form of the unitary matrices in the splitters (Shapiro, 1983),

$$S_L = S_R = \begin{pmatrix} 0 & -\frac{1}{\sqrt{2}} & -\frac{1}{\sqrt{2}} \\ -\frac{1}{\sqrt{2}} & \frac{1}{2} & -\frac{1}{2} \\ -\frac{1}{\sqrt{2}} & -\frac{1}{2} & \frac{1}{2} \end{pmatrix}. \quad (18)$$

Current conservation implies that $|t|^2 + |r|^2 = 1$. Another test is that the conductance through the interferometer $G(\phi) = 2 \frac{e^2}{h} |t(\phi)|^2$ (the factor 2 is due to spin degeneracy) should be a symmetric and periodic function of ϕ with period 1

$$G(\phi) = G(-\phi), \quad G(\phi) = G(\phi + 1). \quad (19)$$

The first equality is a special case of a more general set of constraints resulting from the combination of time-reversal invariance and magnetic field reversal, known as *Onsager relations* (Onsager, 1931). The second relation, the periodicity of $G(\phi)$, is a consequence of gauge invariance, as demonstrated in the *Byers–Yang theorem* (Byers and Yang, 1961; Bloch, 1970). As already discussed above, it states that every physical quantity that is measured in a system which is not simply connected and threaded by a magnetic flux Φ_{AB} is a periodic function of Φ_{AB} with period given by the flux quantum $\Phi_0 = hc/e$.

This system is a beautiful manifestation of the Aharonov–Bohm effect, and, in addition, reveals numerous fundamental concepts in quantum mechanics (Gefen et al., 1984; van Oudenaarden et al., 1998; Cheung et al., 1989; Entin-Wohlman and Gefen, 1989; Aharony et al., 2002, 2003; Entin-Wohlman et al., 2004; Aharony et al., 2005, 2006, 2014, 2019). The example analyzed above involves only two-port systems. The scattering theory and Aharonov–Bohm effect in multi-port systems have been developed in Büttiker (1985), Büttiker (1986), Imry (1986), Avishai and Band (1987), Büttiker (1988), Büttiker (2001), Büttiker (1992), and Cernicchiaro et al. (1997).

The Aharonov–Bohm effect was predicted to be a possible tool for identifying the set of sites visited by a wave packet such that for particular values of the magnetic flux, the wave packet is bound, and this effect is referred to as Aharonov–Bohm caging (Vidal et al., 1998, see also Vaidman, 2000). This effect was recently observed in cold atom systems (Li et al., 2022). Peculiar aspects of the Aharonov–Bohm effect in graphene are reported by Recher et al. (2007) and Rycerz and Beenakker (2007), and in molecular physics by Sjoqvist (2014). Recently, two experiments were performed manifesting the Aharonov–Bohm effect in the study of anyons (Ronen et al., 2021) (using a Fabry–Pérot quantum Hall interferometer), and (Hemanta et al., 2023) using a Mach–Zehnder interferometer. Both experiments exposed the unconventional exchange statistics of these exotic quasiparticles which occur only in two-dimensional systems, and play a crucial role in the fractional quantum Hall effect. The latter experiment also studies the braiding phases of anyons.

Aharonov–Casher effect

The Aharonov–Casher effect (Aharonov and Casher, 1984; Aharonov et al., 1988; Bergsten et al., 2006; Rohrllich, 2009) is an astounding quantum phenomena which is related to the Aharonov–Bohm effect. The relation is sketched in Fig. 4. The Aharonov–Casher effect occurs when a particle with nonzero magnetic moment $\boldsymbol{\mu} = g\mu_B \mathbf{S}/\hbar$ moves in a doubly connected region and is affected by an *electric field* that leads to spin–orbit interaction. The particle need not be charged. It can be an electron (König et al., 2006), a neutron (Cimmino et al., 1989), a magnetic vortex (Elion et al., 1993), or a neutral atom with nonzero spin. An essential point is that no force acts on the particle. In condensed matter physics, the effect is mainly relevant for electrons (Mathur and Stone 1992; Bogachek and Landman 1994; Frustaglia and Richter 2004; Saarikoski et al. 2015; Frustaglia and Nitta 2020; Shekhter et al., 2022).

First we consider a simple case wherein an electron moves on a ring threaded through its center by a charged line of charge density λ which is perpendicular to the plane of the ring. The setup is shown in Fig. 4B, where a comparison of the ring geometries of the Aharonov–Bohm (see Fig. 4A) and Aharonov–Casher effects is illustrated.

A heuristic explanation of the role of spin–orbit in the Aharonov–Casher effect (Aharonov and Casher 1984) for charged particles, for example, electrons, goes as follows: A particle (say, an electron of mass m_e), subject to an electric field $\mathbf{E}$ feels, in its rest frame, an effective magnetic field $\mathbf{H}_{\text{eff}} = (\mathbf{v}/c) \times \mathbf{E} = \frac{1}{m_e c} \mathbf{p} \times \mathbf{E}$, where $\mathbf{v}$ is the particle’s velocity and $\mathbf{p}$ is its momentum. This results in an effective Zeeman Hamiltonian, $H_Z \equiv -\boldsymbol{\mu} \cdot \mathbf{H}_{\text{eff}} = g(\mu_B/m_e c)(\mathbf{S}/\hbar) \cdot \mathbf{p} \times \mathbf{E}$, where $g \approx 2$ reflects the anomalous magnetic moment of the electron. For an electron subject to an electric field $\mathbf{E}$, the spin–orbit term of the Hamiltonian is written (in proper Hermitian form) as

Fig. 4 A schematic illustration of the Aharonov–Bohm and Aharonov–Casher effects. (A) Aharonov–Bohm Effect: An electron moving on a metallic ring threaded by a magnetic flux Φ_{AB} . When the electron encircles the ring, its wave function gains a phase $e^{2\pi i \phi}$, where $\phi = \Phi_{AB}/\Phi_0$. The spin of the electron does not play a role. (B) Aharonov–Casher Effect: An electron with magnetic moment $\boldsymbol{\mu}$ moving on a metallic ring threaded by a charged wire of longitudinal charge density λ . This results in a radial electric field $\mathbf{E} = \frac{\lambda}{2} \hat{\mathbf{r}}$ (black arrows), where R is the radius of the ring. When the electron encircles the ring, its wave function (a two component spinor) is multiplied by a unitary matrix $e^{2\pi i \gamma \sigma_z}$ where $\gamma = \frac{g\mu_B \lambda}{2\hbar c}$. The charge of the electron does not play a role here. Taken from Band Y and Avishai Y (2012) Quantum Mechanics with Application to Nanotechnology and Information Science, Elsevier.

$$H_{\text{so}} = \eta(\mathbf{p} \cdot \boldsymbol{\sigma} \times \mathbf{E} + \boldsymbol{\sigma} \times \mathbf{E} \cdot \mathbf{p}), \quad (20)$$

where $\eta = \frac{g\mu_B}{4m_e c}$. For electrons, the Hamiltonian H_{so} appears in the Pauli Hamiltonian (Pauli, 1927), which arises in the context of working out the nonrelativistic limit of the Dirac equation by expanding it in the Foldy–Wouthuysen scheme (Foldy and Wouthuysen, 1950). It is responsible for a myriad of phenomena. In condensed matter physics, this Hamiltonian is related to the Rashba Hamiltonian (Rashba, 2006; Engel et al., 2006). In contrast with the Hamiltonian H defined in Eq. (6), the Hamiltonian H_{so} is invariant under time reversal that reverses the signs of both $\mathbf{p}$ and $\boldsymbol{\sigma}$.

A simple example of the Aharonov–Casher effect is illustrated by considering the ring geometry shown in Fig. 4B. An electron moving on a ring of radius R experiences a static electric field $\mathbf{E} = \frac{\lambda}{L} \hat{\mathbf{r}}$ produced by a uniformly charged wire with constant charge per unit length λ , stretched along the z -axis passing through the ring's center (here, $L = 2\pi R$). It is instructive to write the Hamiltonian in a form similar to that of Eq. (6),

$$\mathcal{H} = \frac{\mathbf{p}^2}{2m_e} + H_{\text{so}} = \frac{1}{2m_e} \left(\mathbf{p} + \frac{g\mu_B}{2c} \boldsymbol{\sigma} \times \mathbf{E} \right)^2 - \frac{(g\mu_B \mathbf{E})^2}{8m_e c^2}. \quad (21)$$

The term $(\mathbf{p} + \frac{g\mu_B}{2c} \boldsymbol{\sigma} \times \mathbf{E})$ is the *covariant* $SU(2)$ momentum (a 2×2 matrix in spin space), in which the factor $\frac{g\mu_B}{2} \boldsymbol{\sigma} \times \mathbf{E}$ is proportional to an $SU(2)$ vector potential. In the ring geometry of Fig. 4B, the magnitude of the electric field is constant but its direction is angle dependent—it points radially outward, $\mathbf{E} = (\lambda/L) \hat{\mathbf{r}}$. The last term on the RHS of (21) is a constant, $\bar{e} = \frac{(g\mu_B \mathbf{E})^2}{8m_e c^2}$. The Schrödinger equation for an electron on the ring involves only the angular direction $\hat{\theta}$ along the ring, $\boldsymbol{\sigma} \times \mathbf{E}$ is proportional to σ_z , so

$$\frac{1}{2m_e} \left(p_\theta + \frac{e}{c} \frac{\Phi_{\text{AC}}}{L} \sigma_z \right)^2 \psi = \varepsilon(\Phi_{\text{AC}}) \psi, \quad \Phi_{\text{AC}} \equiv \frac{g\mu_B \lambda}{2e}. \quad (22)$$

where p_θ is the tangential momentum and the Aharonov–Casher phase $\Phi_{\text{AC}} \equiv \frac{g\mu_B \lambda}{2e}$ has units of magnetic flux. Thus, in this simple example, the operator

$$A_\theta \equiv \frac{g\mu_B \lambda}{2eL} \sigma_z = \frac{\Phi_{\text{AC}}}{L} \sigma_z \quad (23)$$

can be viewed as a tangential component of a 2×2 matrix $SU(2)$ vector potential. The similarity of (6) and (22) is evident. In Eq. (6), Φ_{AB}/L is the vector potential on the ring responsible for the Aharonov–Bohm effect, whereas in Eq. (22), $\Phi_{\text{AC}} \sigma_z / L$ can be interpreted as a 2×2 matrix vector potential on the ring responsible for the Aharonov–Casher effect. This analogy is not perfect because in the latter case, the energy eigenvalue contains a constant $\bar{e} = \left[\frac{e}{c} \frac{\Phi_{\text{AC}}}{L} \right]^2$; hence strictly speaking, $\varepsilon(\Phi_{\text{AC}})$ is not periodic in Φ_{AC} . However, the ratio between $\bar{e}$ and the kinetic energy at the Fermi momentum p_F can be shown to be extremely small; it is legal to assume that $\bar{e}$ can safely be neglected. Then, Φ_{AB}/L and $\Phi_{\text{AC}} \sigma_z / L$ appear on the same footing as $U(1)$ and $SU(2)$ vector potentials, respectively.

The energy spectrum can be understood in analogy with the discussion of the spectrum of the Aharonov–Bohm system of electrons on a ring. The wave functions for spin-up electrons ($|+\rangle \equiv |\uparrow\rangle$) and spin-down electrons ($|-\rangle \equiv |\downarrow\rangle$) are $\psi_n^{(\pm)}(x) = L^{-1} e^{ik_n x} |\pm\rangle$, where $k_n = \frac{2\pi n}{L}$ with $n = 0, \pm 1, \pm 2, \dots$, and the energy eigenvalues are

$$E_n^{(\pm)} = \frac{\hbar^2}{2m_e R^2} (n \pm \gamma)^2 - \bar{E} = \frac{\hbar^2}{2m_e R^2} (n^2 \pm 2n\gamma), \quad (24)$$

where $\gamma = \Phi_{\text{AC}}/\Phi_0 = \frac{g\mu_B \lambda}{2\hbar c} = \frac{ge\lambda}{2\pi m_e c^2}$, and $\bar{E} = \frac{(g\mu_B \mathbf{E})^2}{8m_e c^2} = \frac{\hbar^2 \gamma^2}{2m_e R^2}$.

Aharonov–Casher effect and non-Abelian gauge transformations

The example discussed above and illustrated in Fig. 4B is a simple particular case wherein the vector potential $\frac{g\mu_B \lambda}{2eL} \sigma_z$ involves a *single Pauli matrix* and a line integral between two points, for example, $\int_{x_q}^{x_p} e^{-i\frac{e}{\hbar c} \frac{\Phi_{\text{AC}}}{L} \sigma_z} dx$, makes sense. Generically, (as shown below) $SU(2)$ vector potentials depend on space point $\mathbf{r}$. The components of the $SU(2)$ vector potential along a line involve combinations of Pauli matrices such as $a_x(\mathbf{r})\sigma_x + a_y(\mathbf{r})\sigma_y + a_z(\mathbf{r})\sigma_z$, where the coefficients are real numbers. Thus, in the language of non integrable phase factors, the phase factor A_{pq} , Eq. (5), is an element of the $U(1)$ gauge Abelian group represented here by complex numbers on the unit circle. On the other hand, in the Aharonov–Casher effect, we encounter the case where nonintegrable phase factors require integration along a given curve connecting points p and q that should be path ordered, that is, the $SU(2)$ nonintegrable phase factor is

$$\eta_{pq} = \left[\int_{r_q}^{r_p} e^{-i\frac{e}{\hbar c} \mathbf{A} \cdot d\mathbf{r}} \right]_{\text{path ordered}}, \quad (25)$$

Gauge theories play a central role in many fields of modern physics. Non-Abelian gauge theories were introduced into physics in a seminal paper (Yang and Mills, 1954).

Fig. 5 Two cases where an electron on a ring is subject to an electric field that is responsible for spin–orbit coupling. (A) As in Fig. 4B, the electron is subject to a *radial electric field* $\mathbf{E} = E\hat{\mathbf{r}}$ generated by an infinite uniformly charged wire stretched along the ring axis. In its rest frame, the electron feels a constant effective magnetic field along $\hat{\mathbf{z}}$. In (B), the electric field (generated, e.g., by a gate voltage) is perpendicular to the ring $\mathbf{E} = E\hat{\mathbf{z}}$. Note that in (A) the effective magnetic field is constant and the phase factor is calculated by an ordinary integral. However, in (B) the electric field generates a *position-dependent effective magnetic field*, and the phase factor is calculated by a path-ordered integral as in Eq. (25). The pertinent coupling is referred to as *Rashba spin–orbit coupling*. Taken from Avishai Y, Totsuka K, and Nagaosa N (2019) AharonovCasher Phase Factor in Mesoscopic Systems. Journal of the Physical Society of Japan 88(8): 084705.

Examples in condensed matter physics

Let us consider an electron moving on a metallic ring of radius R lying on the plane $z = 0$ centered at the origin of the x - y plane (Meijer et al., 2002). Its position is specified by the polar vector $\mathbf{r} = (R, \theta)$ (see Fig. 5B).

The electron is subject to an electric field $\mathbf{E} = E\hat{\mathbf{z}} \perp \hat{\boldsymbol{\theta}}$. Introducing R as the length unit enables us to rewrite the corresponding Schrödinger equation for the electron on the ring in terms of dimensionless quantities. The mechanical momentum is $p_\theta = -i\frac{d}{d\theta}$. Within the SU(2) formulation of the Pauli equation (Pauli, 1927; Anandan, 1989; Fröhlich and Studer, 1993), the SU(2) vector potential in the ring geometry takes the form

$$\mathbf{A}(\theta) = \beta(\theta)\hat{\mathbf{E}}(\theta) \times \boldsymbol{\sigma}, \quad (26)$$

where the real parameter $\beta(\theta)$ specifies the strength of the local spin–orbit coupling (Meir et al., 1989, 1990; Entin-Wohlman et al., 1992) (compare with Eq. (23) applicable for case Fig. 5B). For simplicity it is assumed that β is independent of θ . For example, if the Rashba Hamiltonian [relevant for the present discussion based on figure 5 (b)] is written as $H_R = -\alpha_R(\boldsymbol{\sigma} \times \mathbf{p}) \cdot \hat{\mathbf{E}}$ (where $\alpha_R = -\frac{1}{2mc}g\mu_B|E|$ is the Rashba SOC strength parameter), then $\beta = 2mR\alpha_R/\hbar^2$.

In the present ring geometry, $\mathbf{k}$ is parallel to the tangential unit vector $\hat{\boldsymbol{\theta}}$ and we are concerned only with the tangential component of $\mathbf{A}(\theta)$, that is an element of the su(2)-algebra,

$$\mathcal{A}(\theta) = \mathbf{A}(\theta) \cdot \hat{\boldsymbol{\theta}} = \beta[\hat{\boldsymbol{\theta}} \times \hat{\mathbf{E}}] \cdot \boldsymbol{\sigma} \equiv \beta \hat{\mathbf{n}} \cdot \boldsymbol{\sigma} \in [\text{su}(2)]. \quad (27)$$

Classically, $\hat{\boldsymbol{\theta}} \parallel \mathbf{v}$ (where $\mathbf{v}$ is the electron velocity) so that $\hat{\mathbf{n}}$ points along $\mathbf{E} \times \mathbf{v}$ that is the direction of the effective magnetic field $\mathbf{B}_{\text{eff}}$ felt by the electron in its rest frame. Quantum mechanically, $\hat{\mathbf{n}}$ encodes the nature of the spin–orbit coupling. In our example for electrons on a ring subject to a perpendicular electric field, $\hat{\mathbf{n}} = \hat{\boldsymbol{\theta}} \times \hat{\mathbf{E}}$. In two-dimensional semiconductors, it is possible to have also an intrinsic spin–orbit coupling (Engel et al., 2006). In one simplified form (Dresselhaus, 1955), derived from the Kane model of $\mathbf{k} \cdot \mathbf{p}$ perturbation theory (Kane, 1957), $\hat{\mathbf{n}}$ is defined through $\hat{\mathbf{n}} \cdot \boldsymbol{\sigma} = \cos\theta \sigma_x - \sin\theta \sigma_y$ (Engel et al. 2006, Eq. (8)). With the unit vector $\hat{\mathbf{n}}$, the SU(2)-invariant Schrödinger equation (in dimensionless units) for the spinor $\psi(\theta) = \begin{pmatrix} \psi_1(\theta) \\ \psi_2(\theta) \end{pmatrix}$ is written as:

$$\left[-i\frac{d}{d\theta} + \beta \hat{\mathbf{n}}(\theta) \cdot \boldsymbol{\sigma} \right]^2 \psi(\theta) = \varepsilon \psi(\theta), \quad (28)$$

where $\varepsilon = \frac{2mR^2}{\hbar^2} \mathcal{E} \equiv k^2$, with $\mathcal{E}$ being the electron energy in physical units.

Now we are in a position to express the nonintegrable phase factor. If the SU(2) vector potential is changed from θ to $\theta + d\theta$ along an infinitesimal directed arc $d\ell = R\hat{\boldsymbol{\theta}}d\theta$, it gains an SU(2) *matrix-valued* phase factor according to

$$\mathbf{A}(\theta + d\theta) = e^{i\beta \hat{\mathbf{n}}(\theta) \cdot \boldsymbol{\sigma} d\theta} \mathbf{A}(\theta). \quad (29)$$

If the spin–orbit coupling strength β and/or the unit vector $\hat{\mathbf{n}}$ depend on the position θ , two phase factors do not commute. Thus, the SU(2) non integrable phase factor accumulated from $\theta = 0$ up to a finite angle θ is given by the following path-ordered integral, or equivalently, an ordered product of infinitesimal phase factors (Wu and Yang 1975, Anandan 1989). The *non-Abelian* gauge transformation $\psi(\theta) \rightarrow \xi(\theta)$ that eliminates the vector potential is

$$\begin{aligned}\psi(\theta) &= \mathcal{P} \exp \left\{ \int_0^\theta i\beta \hat{\mathbf{n}}(\theta') \cdot \boldsymbol{\sigma} d\theta' \right\} \xi(\theta) \\ &= \lim_{N \rightarrow \infty} \left\{ \prod_{j=1}^N e^{i\beta \hat{\mathbf{n}}(j\Delta\theta) \cdot \boldsymbol{\sigma} \Delta\theta} \right\} \xi(\theta) \equiv A_{AC}[\theta; \beta] \xi(\theta),\end{aligned}\quad (30)$$

where $\mathcal{P}$ is path ordering, $\Delta\theta = \theta/N$, and the arrow $\leftarrow$ means that matrices are multiplied from the right to the left. The 2×2 matrix function $A_{AC}[\theta; \beta]$ satisfies a first-order differential equation that can be solved analytically (Avishai et al., 2019). The function $\xi(\theta)$ then satisfies Eq. (28) in the absence of the vector potential. The procedure of multiplying phase factors as in Eq. (30) and defining λ_{AC} by Eq. (31) can be extended straightforwardly to any continuous closed curve.

Since the gauge transformation $A_{AC}[\theta; \beta]$ is an SU(2) matrix, it can be written as $A_{AC}[\theta; \beta] = e^{i\lambda(\theta, \beta) \hat{\mathbf{b}}[\theta, \beta] \cdot \boldsymbol{\sigma}}$, where $\lambda(\theta, \beta)$ and the two dimensional unit vector $\hat{\mathbf{b}}[\theta, \beta]$ should be calculated within a given spin–orbit coupling scheme (see for example, the analysis of the scattering in the square geometry below). The Aharonov–Casher phase λ_{AC} is here defined as a single number in terms of the SU(2) phase acquired along the entire circle:

$$F_{AC}[2\pi; \beta] = \mathcal{P} \exp \left\{ \oint i\beta \hat{\mathbf{n}}(\theta') \cdot \boldsymbol{\sigma} d\theta' \right\} \equiv e^{i\lambda_{AC} \hat{\mathbf{b}} \cdot \boldsymbol{\sigma}} = \underbrace{\cos \lambda_{AC}}_{\text{nonvanishing trace}} \mathbf{1}_{2 \times 2} + \underbrace{i \sin \lambda_{AC}}_{\text{traceless}} \hat{\mathbf{b}} \cdot \boldsymbol{\sigma}. \quad (31)$$

Consequently, three real parameters, that is, the angle λ_{AC} and the two-component unit vector $\hat{\mathbf{b}}$ determine the Aharonov–Casher phase factor unambiguously. The wave function $\psi(\theta) = A_{AC}[\theta; \beta] \xi(\theta)$ should be periodic, that is, $\psi(2\pi) = \psi(0)$, and this equality determines the energy eigenvalues.

In analogy with persistent charge current discussed in relation to the Aharonov–Bohm effect we encounter here the possible occurrence of *spin current* (Sun and Xie 2005; Niu 2006). It is formally defined as $J_S(\theta) = \frac{1}{2} \psi^\dagger(\theta) \{ \mathbf{v}, \boldsymbol{\sigma} \} \psi(\theta)$, where $\mathbf{v} = [-i \frac{d}{d\theta} + \beta \hat{\mathbf{n}}(\theta) \cdot \boldsymbol{\sigma}]$ is the velocity operator. Unlike charge current, spin current is time reversal invariant and (generically) space dependent.

Aharonov–Casher interferometer in a perpendicular electric field

Having studied the physics of an Aharonov–Bohm interferometer, it is expected, following an experiment by Borunda et al. (2008), that there is an analogous system for the Aharonov–Casher effect. The setup of a simple example of Aharonov–Casher interferometer is illustrated in Fig. 6. To write down the Schrödinger equation, we use, as before, dimensionless quantities. The electron wave function at point $\mathbf{r}$ (any point on the ring or on either wire) for a boundary condition that an initial incoming electron has spin projection σ is expressed as a spinor: $\Psi_\sigma(\mathbf{r}) = \begin{pmatrix} \psi_{1\sigma}(\mathbf{r}) \\ \psi_{2\sigma}(\mathbf{r}) \end{pmatrix}$. The two spinors for the spin projections $\sigma = \uparrow, \downarrow$ of the incoming electron can be arranged into a 2×2 wave function matrix

$$\Psi(\mathbf{r}) = \begin{pmatrix} \psi_{\uparrow\uparrow}(\mathbf{r}) & \psi_{\uparrow\downarrow}(\mathbf{r}) \\ \psi_{\downarrow\uparrow}(\mathbf{r}) & \psi_{\downarrow\downarrow}(\mathbf{r}) \end{pmatrix},$$

Fig. 6 Aharonov–Casher Interferometer: Similar to Fig. 3, two wires at different potentials $V_L \gtrless V_R$ are connected to a metallic ring. Electrons approaching the ring from the left at polar angle $\theta = 0$ are partially reflected back to the left wire and partially transmitted to the right wire at polar angle $\theta = \alpha$ (reflection matrix r and transmission matrix t). The ring is subject to a perpendicular electric field so that the Rashba spin–orbit mechanism generates an effective magnetic field along the radial direction $\hat{\mathbf{n}}(\theta) = (\cos \theta, \sin \theta, 0)$ (Fig. 5B). The electric field is *homogeneous and acts only on the circular area confined by the ring*. The local phase factor for **any** polar angle θ is $e^{i\beta \hat{\mathbf{n}}(\theta) \cdot \boldsymbol{\sigma}}$. Taken from Avishai et al. (2019), where an analysis of Aharonov–Casher interferometer subject to some version of Dresselhaus spin–orbit coupling is also analyzed. Taken from Avishai Y, Totsuka K, and Nagaosa N (2019) Aharonov–Casher Phase Factor in Mesoscopic Systems. Journal of the Physical Society of Japan 88(8): 084705.

so we have

$$\begin{cases} -\frac{d^2}{dx^2} \Psi(x) = k^2 \Psi(x), & (\text{when the electron is on left or right wire}) \\ [-i\frac{d}{d\theta} - \beta \hat{\mathbf{n}}(\theta) \cdot \boldsymbol{\sigma}]^2 \Psi(\theta) = k^2 \Psi(\theta) & (\text{when the electron is on the ring}). \end{cases} \quad (32)$$

We consider an electron with spin projection $\sigma = \uparrow, \downarrow$ approaching the ring from the left wire at energy $\varepsilon = k^2$. It is partly transmitted into the right wire with spin projection $\mu = \uparrow, \downarrow$ and partly reflected back into the left wire with $\mu = \uparrow, \downarrow$. The corresponding matrix elements of the 2×2 transmission and reflection matrices are $t_{\mu\sigma}, r_{\mu\sigma}$, explicitly

$$t = \begin{pmatrix} t_{\uparrow\uparrow} & t_{\uparrow\downarrow} \\ t_{\downarrow\uparrow} & t_{\downarrow\downarrow} \end{pmatrix} \quad r = \begin{pmatrix} r_{\uparrow\uparrow} & r_{\uparrow\downarrow} \\ r_{\downarrow\uparrow} & r_{\downarrow\downarrow} \end{pmatrix}.$$

The technique for calculating t and r is similar to that used in the Aharonov–Bohm interferometer, but is slightly more complicated. The conductance through the interferometer is given by the Landauer formula (Landauer, 1957), $g = \frac{e^2}{h} \text{Tr}[t^\dagger t]$.

Fig. 7 plots the cosine of the Aharonov–Casher phase λ_{AC} and the conductance g (in units of $\frac{e^2}{h}$) as a function of the spin–orbit strength β for two values of the right splitter angle α .

Conductance and polarization in transmission through a square interferometer

It was shown in the discussion of Eq. (31) that the $SU(2)$ phase factor $e^{i\lambda_{AC}\hat{\mathbf{b}} \cdot \boldsymbol{\sigma}}$ can be written as a sum of two 2×2 matrices, one has nonvanishing trace and one is traceless. Both depend on the Aharonov–Casher phase λ_{AC} , but the role of the traceless term (in particular the unit vector $\hat{\mathbf{b}}$) was not explained. Using a relatively simple tight-binding model that can be solved analytically, it will be shown that this term is responsible for electron polarization. Note that spin–orbit coupling obeys time reversal invariance but the specification of scattering boundary condition destroys it so that polarization is feasible (Meijer et al., 2005; Entin-Wohlman et al., 2010; Nagasawa et al., 2012, 2013; Avishai and Band, 2017).

It can be shown (Avishai et al., 2019) that in two-port systems like the Aharonov–Casher interferometer discussed above, there is no polarization in the outgoing lead (assuming that the incoming beam is not polarized). Here we show that in a multiport system, it is possible to get a polarized outgoing beam due to Rashba spin–orbit coupling. Consider, as in Fig. 8, a tight-binding model of noninteracting electrons moving along two wires and scattered from a region that carries an $SU(2)$ flux where the phase factors in the product do not commute and depend on the spin–orbit strength. The system is laid on the $x-z$ plane and consists of two chains (metallic wires) numbered $\alpha = 1, 2$ with each chain consisting of sites $-\infty < n < \infty$, which are then connected to each other by the two rungs of the square at $n = 0$ and $n = 1$ (see Fig. 8). A uniform electric field acts along $\hat{\mathbf{y}}$ upon the square, thereby lead to a Rashba spin–orbit coupling along the links of the square. This tight-binding model is treated within the formalism of second quantization.

Fig. 7 Plots of dimensionless conductance g (blue curve) and cosine of the Aharonov–Casher phase $\cos \lambda_{AC}$ (orange curve) as function of spin–orbit strength β for the ring interferometer schematically depicted in Fig. 6. The wave number is set to $kR = 1.25$, and (A) $\alpha = \pi$, and (B) $\alpha = 1.7$. As a property of the closed loop, λ_{AC} is independent of α . The conductance, that also encodes the geometric properties of the interferometer, naturally depends on α , but in both cases it is periodic in the Aharonov–Casher phase λ_{AC} . Taken from Avishai Y, Totsuka K, and Nagaosa N (2019) Aharonov–Casher Phase Factor in Mesoscopic Systems. Journal of the Physical Society of Japan 88(8): 084705.

Fig. 8 Two-channel tight-binding model for electron scattering from a square region in the $x-z$ plane (shown by bold blue lines) subject to a uniform electric field $E\hat{\mathbf{y}}$ acting only on the square. The corresponding $SU(2)$ hopping matrix elements are given by $e^{\pm i\beta\sigma_x}$ along the horizontal links and $e^{\pm i\beta\sigma_z}$ along the vertical links. Taken from Avishai Y, Totsuka K, and Nagaosa N (2019) AharonovCasher Phase Factor in Mesoscopic Systems. Journal of the Physical Society of Japan 88 (8): 084705.

The creation and annihilation operators for the spin projection $\sigma = \uparrow, \downarrow$ are indexed as $c_{\alpha,n,\sigma}^\dagger$ and $c_{\alpha,n,\sigma}$, respectively, and the spin–orbit interaction is active only on the four links forming the square (shown by the bold lines in Fig. 8). The Hamiltonian is written as $H = H_0 + H_1$ with

$$\begin{aligned} H_0 &= -t \sum_{\alpha=1,2} \sum_{n \leq 0} c_{\alpha,-(n+1)}^\dagger c_{\alpha,-n} \\ &\quad - t \sum_{\alpha=1,2} \sum_{n \geq 1} c_{\alpha,(n+1)}^\dagger c_{\alpha,n} + \text{h.c.}, \\ H_1 &= \sum_{n=0,1} c_{1,n}^\dagger e^{-i\beta\sigma_x} c_{2,n} + \sum_{\alpha=1,2} c_{\alpha,0}^\dagger e^{i\beta\sigma_z} c_{\alpha,1} + \text{h.c.}, \end{aligned} \quad (33)$$

where $c_{\alpha,n}^\dagger \equiv (c_{\alpha,n,\uparrow}^\dagger, c_{\alpha,n,\downarrow}^\dagger)$.

The solution of the scattering problem yields the 4×4 (2 for spin and 2 for channel) transmission and reflection matrices t and r whose matrix elements $t_{\alpha'\sigma';\alpha\sigma}$ and $r_{\alpha'\sigma';\alpha\sigma}$ give the transmission and reflection amplitudes for scattering of a spin- σ electron impinging from channel α to one in the channel α' with spin projection σ' . They depend on the SOC strength, and the wave number k that determines the energy $\varepsilon = -2t \cos k$. On the other hand, the Aharonov–Casher phase λ_{AC} is a property of the closed loop irrespective of the scattering energy. In the present case, it is given by calculating the product of the four matrices shown in Fig. 8, and using Eq. (31), giving

$$\cos \lambda_{AC}(\beta) = 1 - 2 \sin^4 \beta. \quad (34)$$

Before presenting results related to the scattering problem, it is worthwhile to check the eigenvalue problem of a system of an electron hopping on an isolated square (without wires; the square shown by bold lines in Fig. 8) as a closed system, especially whether they depend only on the Aharonov–Casher phase. The tight-binding Hamiltonian assumes the following form

$$H_{\square} = \begin{pmatrix} 0 & e^{i\beta\sigma_z} & e^{-i\beta\sigma_x} & 0 \\ e^{-i\beta\sigma_z} & 0 & 0 & e^{-i\beta\sigma_x} \\ e^{i\beta\sigma_x} & 0 & 0 & e^{i\beta\sigma_z} \\ 0 & e^{i\beta\sigma_x} & e^{-i\beta\sigma_z} & 0 \end{pmatrix}, \quad (35)$$

where each entry is a 2×2 matrix acting on the spin space at each site of the square. Simple calculations show that there are four different eigenvalues each of which is twofold (Kramers') degenerate:

$$E_{\square} = \pm 2 \cos \frac{\lambda_{AC}(\beta)}{4}, \quad \pm 2 \sin \frac{\lambda_{AC}(\beta)}{4}. \quad (36)$$

In any case, the eigenvalues depend on β only through $\lambda_{AC}(\beta)$ as defined in Eq. (34).

The solution of the scattering problem yields the 4×4 (2 for spin and 2 for channel) transmission and reflection matrices t and r whose matrix elements $t_{\alpha'\sigma';\alpha\sigma}$ and $r_{\alpha'\sigma';\alpha\sigma}$ give the transmission and reflection amplitudes for scattering of a spin- σ electron impinging from channel α to one in the channel α' with spin projection σ' . They depend on the spin–orbit coupling strength β and the wave number k that determines the energy $\varepsilon = -2t \cos k$. Going back to the scattering problem, we will now inspect the relation between the ACP and a couple of experimental observables. Specifically, we are interested in the conductance g and the transmitted polarization vector $\mathbf{P}$, defined as

$$g(k; \beta) = \text{Tr}[t^\dagger t], \quad \mathbf{P} = \frac{\text{Tr}[t^\dagger \boldsymbol{\Sigma} t]}{g}, \quad \boldsymbol{\Sigma} = \mathbf{1}_{2 \times 2} \otimes \boldsymbol{\sigma}. \quad (37)$$

The following expressions for the conductance g and the transmitted polarization P_y are as follows:

$$\begin{aligned} g &= \frac{16(-5 + 4 \cos 2k(1 - \cos \lambda_{AC}) \sin^2 k)}{-17 + 8 \cos 2k + 8(\cos 4k - 4 \cos 2k)(1 - \cos \lambda_{AC}) - 16(1 - \cos \lambda_{AC})^2}, \\ P_y &= \frac{2 \sin 2k(1 - \cos \lambda_{AC})}{5 - 2 \cos 2k(1 - \cos \lambda_{AC})}, \quad P_x = P_z = 0. \end{aligned} \quad (38)$$

When the spin–orbit coupling strength $\beta \rightarrow 0$ then $\lambda_{AC} \rightarrow 0$. The conductance remains finite but the polarization vanishes (as it must). But when $\lambda_{AC} \rightarrow 0$, the traceless part of the Aharonov–Casher phase factor in Eq. (31) tends to zero as well. Hence, this part of the phase factor is related (albeit in a complex way) to an experimental quantity.

Analogy of Aharonov–Bohm effect in cold atoms physics

In the Aharonov–Bohm effect, electrons (charged particles) encircle a magnetic flux in configuration space. There is a beautiful analog pertaining to *neutral atoms*. When cold atoms are subject to a periodic optical potential the corresponding dynamics is similar to that of Bloch electrons in crystals, and the wave functions are Bloch functions at crystal momentum $\mathbf{k}$ and energy $\varepsilon_n(\mathbf{k})$. Since the atoms are neutral, and one cannot speak of Aharonov–Bohm phase. However, moving an atom along a closed curve in $\mathbf{k}$ space endows its wave function with a phase denoted as *Berry phase* (Berry 1984; Xiao et al., 2010).

Thus, in cold atom systems, instead of the Aharonov–Bohm phase, the object of study is the Berry phase, that contains information on the pertinent energy band. In addition, the Berry phase is related to the topological invariant known as the Chern number (Thouless et al., 1982). For a graphene-like optical potential forming a hexagonal lattice, the Berry phase is obtained by moving an atom that encircles a Berry flux along a closed loop C around a Dirac point in momentum space (see Fig. 1 in Duca et al., 2015). For a Bloch function $\psi_{\mathbf{k}}^n(\mathbf{r}) = e^{i\mathbf{k}\cdot\mathbf{r}}u_{\mathbf{k}}^n(\mathbf{r})$ corresponding to an energy band n and lattice momentum $\mathbf{k}$, the analog of the vector potential $\mathbf{A}$ is the *Berry connection* $\mathbf{A}_n(\mathbf{k}) = i\langle u_{\mathbf{k}}^n | \nabla_{\mathbf{k}} | u_{\mathbf{k}}^n \rangle$, and the analog of the magnetic field is the *Berry curvature* $\Omega_n(\mathbf{k}) = \nabla_{\mathbf{k}} \times \mathbf{A}_n(\mathbf{k})$. The Berry phase is then defined as

$$\varphi_n = \oint_C \mathbf{A}_n(\mathbf{k}) d\mathbf{k} = \int_S \Omega_n(\mathbf{k}) d^2k, \quad (39)$$

where S is the area encircled by the curve C in momentum space. The Berry phase includes information on the geometry of the corresponding Bloch band. It is gauge invariant and hence it can be measured. For a graphene hexagonal lattice, the authors of Duca et al. (2015) built an interferometer that enabled the detection of the Berry flux at each Dirac point. Thereby, they could determine the Berry curvature with high momentum resolution.

As it turns out, understanding the physics of multiple bands with degeneracies in topological insulators, requires other concepts beyond the Berry phases. As shown in Li et al. (2016), such systems can be described using the technique of Wilson lines (Yu et al., 2011; Alexandradinata et al., 2014).

Chern numbers are topological invariants that classify bands in topological materials (Hasan and Kane, 2010; Asbóth et al., 2016; Qi and Zhang, 2011; Goldman et al., 2014; Cooper et al., 2019). They can be calculated using the Berry curvature of the band (Fukui et al., 2005). The Chern numbers determine properties of the edge state of materials. This generalization of Aharonov phase has become a very important part of condensed matter physics.

Magnetic monopoles

A magnetic monopole is an elementary particle with a magnetic charge. The existence of a magnetic monopole would violate Gauss's law for magnetism $\nabla \cdot \mathbf{B} = 0$ and help to explain the law of charge quantization as formulated by Dirac (1931). So far, magnetic monopoles have not been observed (Milton, 2006). The theoretical investigation of Dirac monopoles is extremely rich but will not be considered here.

In condensed matter physics (specifically in strongly interacting systems), there are objects that behave as monopole (although they do not exist as elementary particles) are encountered. An example is that of quasi-particles with fractional charge (suggested by Laughlin) in the fractional quantum Hall effect (Willett et al., 2013; Nakamura et al., 2019). In spin ice materials, electron correlations lead to phenomena that are similar to those of magnetic monopoles (e.g., see Castelnovo et al., 2008; Diamantini et al., 2021, and references therein) but, again, they should not be confused with elementary particles having magnetic charge. An experimental imitation of a magnetic monopole at the tip of a long nanoscopically thin magnetic needle was reported in Béch   et al. (2014).

Dirac quantization and phase factors

If a monopole does exist, it is interesting to consider the spectrum of an electron of charge $-e$ in the central field of a monopole of magnetic charge g such that the magnetic field is $\mathbf{B} = g \frac{\mathbf{r}}{r^2}$, and as shown in Wu and Yang (1975), in this case there does not exist a singularity-free vector potential $\mathbf{A}(\mathbf{r})$ in 3D space. To show this, assume the monopole to be fixed at the origin and denote the electron position in spherical coordinates r, θ, φ . Denote by $\Phi(r, \theta)$ the magnetic flux through a cup bounded by the circular loop $r, \theta, 0 \leq \varphi \leq 2\pi$. From Maxwell equations we have,

$$\Phi(r, \theta) = \oint A_{\varphi}(r, \theta) d\varphi. \quad (40)$$

Evidently, $\Phi(r, \theta) = 2\pi g(1 - \cos \theta)$. For $\theta = 0$ (the north pole) we indeed get $\Phi(r, 0) = 0$, which is reasonable, but for $\theta = \pi$ (the south pole) we get $\Phi(r, \pi) = 4\pi g$ which is not reasonable because the length of the loop is zero. Thus A_{φ} is singular at $\theta = \pi$ and the concept of phase factors introduced in the "Gauge invariance" section should be reexamined. This singularity is sometimes termed as the *Dirac string*.

The solution to this contradiction (Wu and Yang, 1975) is to divide the spherical shell for fixed r and φ into three regions, $0 \leq \theta \leq \frac{\pi}{2} - \delta$, $\frac{\pi}{2} - \delta \leq \theta \leq \frac{\pi}{2} + \delta$ and $\frac{\pi}{2} + \delta \leq \theta \leq \pi$ where $0 < \delta < \frac{\pi}{2}$. In the first and third regions, the corresponding vector potentials are,

$$\begin{aligned} A_{\varphi}(r, \theta) &= \frac{g}{r \sin \theta} (1 - \cos \theta) & 0 \leq \theta \leq \frac{\pi}{2} - \delta, \\ A_{\varphi}(r, \theta) &= \frac{-g}{r \sin \theta} (1 + \cos \theta) & \frac{\pi}{2} + \delta \leq \theta \leq \pi, \end{aligned} \quad (41)$$

so that there is no singularity, not at $\theta = 0$ nor at $\theta = \pi$. In the overlap region the two vector potentials are related by a gauge transformation

$$S(\varphi) = e^{\frac{2ige}{\hbar c}\varphi}. \quad (42)$$

Since $S(\varphi)$ must be uniquely defined we must have the Dirac quantization rule,

$$\frac{2ge}{\hbar c} = n = \text{integer}. \quad (43)$$

Wu and Yang then show that if Dirac quantization holds, the concept of phase factors is valid for the description of electromagnetism also if monopoles do exist. In a subsequent paper (Wu and Yang, 1976) the authors introduced the concept of *Dirac monopole without strings*.

Tight-binding spectra on spherical graphs: Avoiding the Dirac string

We now analyze a tight-binding model for an electron in the field of a magnetic monopole, in which the Dirac string is avoided (Avishai and Luck, 2008a). It is based on the use of the *group* $U(1)$ (whose elements are the phase factors) and not on its *algebra* (whose elements are the path integrals of the vector potentials). The simplest example of this model is that of an electron hopping on the vertices of a tetrahedron at whose center there is a magnetic monopole of magnetic charge $g = \frac{n\hbar c}{2e}$. The tetrahedron has $V = 4$ vertices, $F = 4$ faces, and $L = 6$ links. According to Euler theorem $L = F + V - 2$. Denote by $a_i^\dagger$ and a_i the creation and annihilation operators of the electron on vertex i , and by U_{ij} the phase factor between two adjacent vertices i, j by U_{ij} (these are elements of the gauge group $U(1)$ living on these links). The tight-binding Hamiltonian of the system is

$$\hat{\mathcal{H}} = \sum_{\langle ij \rangle} a_i^\dagger U_{ij} a_j + h.c., \quad (44)$$

where the sum runs over the $L = 6$ oriented links $\langle ij \rangle$ of a tetrahedron. The Hamiltonian $\hat{\mathcal{H}}$ is complex, i.e., it is not invariant under time reversal. One has

$$U_{ij} = U_{ji}^{-1} = U_{ji}^*. \quad (45)$$

The product of the phase factors around *each face* is related to the outgoing magnetic flux φ through this face as

$$U_{ij}U_{jk}U_{ki} = e^{(2\pi i\varphi/\Phi_0)}, \quad (46)$$

where $\Phi_0 = \frac{\hbar c}{e}$ is the quantum flux unit. By Gauss's theorem the total outgoing magnetic flux is $\Phi = 4\pi g$ so that $\varphi = \pi g$. The Hamiltonian $\hat{\mathcal{H}}$ is thus represented by a $V \times V = 4 \times 4$ complex Hermitian matrix $\mathcal{H}$ such that $\mathcal{H}_{ij} = U_{ij}$. It is easy to check that $\text{tr}\mathcal{H} = 0$ and $\text{tr}\mathcal{H}^2 = 2L = 12$. The main step in the explicit construction of the Hamiltonian matrix consists in finding a configuration of the gauge field, i.e., a set of phase factors U_{ij} , so that Eq. (46) is satisfied. This procedure is carried out in Avishai and Luck (2008a) and results in the spectrum shown in Table 1.

Calculations are reported for the five platonic solids tetrahedron, cube, octahedron, dodecahedron, icosahedron (for which the spectrum is periodic in the number of faces F , namely $E(n + F) = E(n)$, $n = 0, 1, \dots, F - 1$), and the fullerene (for which the spectrum is *not periodic* in n because the ratio between the areas of a hexagon and a pentagon is not a rational number).

Relation to Aharonov–Casher effect

In Avishai and Luck (2008b), the authors investigate a tight-binding model for an electron confined to move on a two-dimensional surface with spherical topology and subject to a spin-orbit interaction. The latter is assumed to be generated by the radial electric field produced by a static point charge sitting at the center of the sphere. The tight-binding Hamiltonian considered is a discretization of the familiar form of the spin-orbit Hamiltonian $L \cdot S$. It involves $SU(2)$ hopping matrices (phase factors) of the form $\exp(i\mu \mathbf{n} \cdot \boldsymbol{\sigma})$ living on the oriented links of the graph and $\mathbf{n}$ is a unit vector along the link. For a given structure, the dimensionless coupling constant μ is the only parameter of the model (see below the expression for μ).

Table 1 Energy levels E of the tetrahedron and their multiplicities m , for each value of the magnetic charge n over one period.

n	E	m
0	3	1
	-1	3
1,3	$\sqrt{3}$	2
	$-\sqrt{3}$	2
2	1	3
	-3	1

For definiteness let us consider an electron hopping on the vertices A, B, C, D of a tetrahedron (a spherical graph of sphere radius R), at whose center O there is a charge $q = Ze$. Denote by Θ the angle of the triangle $A\hat{O}B$. The tight-binding model is defined by means of the Hamiltonian

$$\hat{\mathcal{H}} = \sum_{(AB)} \left(a_A^\dagger U_{AB} a_B + \text{h.c.} \right), \quad (47)$$

where the sum runs over the six oriented links (AB) of the tetrahedron, whereas

$$a_A^\dagger = \begin{pmatrix} a_{A\uparrow}^\dagger & a_{A\downarrow}^\dagger \end{pmatrix}, \quad a = \begin{pmatrix} a_{A\uparrow} \\ a_{A\downarrow} \end{pmatrix} \quad (48)$$

are respectively the electron creation and annihilation operators at site A , and the matrices U_{AB} are elements of the non-Abelian gauge group $SU(2)$, i.e., 2×2 unitary matrices with unit determinant, describing the spin-orbit coupling on an electron hopping from site A to a neighboring site B . In analogy with the Abelian case the phase factor U_{AB} is expressed as a *path-ordered integral*:

$$U_{AB} = P \exp \left\{ -ig \int_{\gamma(A,B)} (\mathbf{E} \times \boldsymbol{\sigma}) \cdot d\mathbf{r} \right\}, \quad (49)$$

where

$$g = \frac{e}{4mc^2}, \quad \mathbf{E} = q \frac{\mathbf{r}}{r^3}. \quad (50)$$

and $\gamma(A, B)$ is a curve joining A and B . If the path $\gamma(A, B)$ is planar, i.e., entirely contained in the OAB plane. In this case, at every point of the path the infinitesimal vector $\mathbf{r} \times d\mathbf{r}$ is perpendicular to the latter plane, i.e., aligned with the vector $\mathbf{n}_{AB} = \hat{\mathbf{A}} \times \hat{\mathbf{B}}$. As a consequence, the path-ordering prescription is not needed, and Eq. (49) can be recast as an *ordinary integral*

$$\begin{aligned} U_{AB} &= \exp \left\{ igq \left(\int_{\gamma(A,B)} \frac{\mathbf{r} \times d\mathbf{r}}{r^3} \right) \cdot \boldsymbol{\sigma} \right\}, \\ &= \exp(i\mu(\Theta) \mathbf{n}_{AB} \cdot \boldsymbol{\sigma}) = \cos \mu + i \sin \mu \mathbf{n}_{AB} \cdot \boldsymbol{\sigma}. \end{aligned} \quad (51)$$

The functional form of $\mu(\Theta)$ depends on the form of the planar curve $\gamma(A, B)$. Intuitively, we can choose either a link or an arc of a great circle joining A and B . Consequently, we are left with the following expression for the parameter μ , for both choices of the path $\gamma(A, B)$:

$$\mu(\Theta) = \varepsilon \times \begin{cases} 2 \tan(\Theta/2) & (\text{path along link}), \\ \Theta & (\text{great-circle path}) \end{cases} \quad (52)$$

with

$$\varepsilon = \frac{gq}{R} = \frac{qe}{4mc^2 R}, \quad q = Ze. \quad (53)$$

An analysis of the energy spectrum is carried out for the five Platonic solids (tetrahedron, cube, octahedron, dodecahedron, and icosahedron) and the C_{60} Fullerene. Except for the latter, the μ -dependence of all the energy levels is obtained analytically in closed form (Table 2).

Special values of μ . The following two values of the parameter μ :

$$\mu_0 = \Theta/2, \quad \mu_1 = \Theta/2 + \pi, \quad (54)$$

are special in several respects. First, the $\mu \leftrightarrow \Theta - \mu$ symmetry and the semi-periodicity imply that μ_0 and μ_1 are symmetry axes of the energy spectrum, if displayed as a function of μ . Second, the Kramers degeneracy and the $\mu \leftrightarrow \Theta - \mu$ symmetry imply that all energy levels are at least fourfold degenerate, i.e., that all the multiplicities are integer multiples of 4. Third, there is a striking

Table 2 Energy levels $E_a(\mu)$ of the tetrahedron and their multiplicities m_a . Horizontal lines separate groups of levels related to each other by the $\mu \leftrightarrow \Theta - \mu$ symmetry.

a	E_a	m_a
1	$3 \cos \mu$	2
2	$-\cos \mu + 2\sqrt{2} \sin \mu$	2
3	$\sqrt{3}$	2
	$-\sqrt{3}$	2
3	$-\cos \mu - 2\sqrt{2} \sin \mu$	4

Fig. 9 Energy levels E of the tetrahedron as a function of the magnetic charge n over one period. Line segments show how individual levels ‘jump’ as n is increased by one unit.

Fig. 10 Plot of the energy spectrum of the tetrahedron against $\mu/(2\pi)$ over one period. Vertical dashed lines: symmetry axes at the special values of μ given in Eq. (54). The energies at the intersection point of the first vertical dashed line are identical with the two energies corresponding to the energies of an electron in the field of $n = 1$ quantized magnetic dipole, shown in Fig. 9.

correspondence between the present problem at the special value μ_0 and the tight-binding problem in the presence of a magnetic monopole investigated in “Tight-binding spectra on spherical graphs: Avoiding the Dirac string” subsection. For the symmetric point $\mu = \Theta/2$, the problem can be exactly mapped onto a tight-binding model in the presence of the magnetic field generated by a Dirac monopole, studied in “Tight-binding spectra on spherical graphs: Avoiding the Dirac string” subsection. Thus, in Fig. 10, the energies at the intersection point of the first vertical dashed line are identical with the two energies corresponding to the energies of an electron in the field of $n = 1$ quantized magnetic dipole, shown in Fig. 9. This result, proved analytically in Avishai and Luck (2008b), is a beautiful manifestation of the relation between Aharonov–Bohm and Aharonov–Casher effects.

Conclusion

Aharonov–Bohm and Aharonov–Casher effects substantiate the fundamental role of quantum mechanics as a solid theory of Nature (Richter, 2012). In addition, they expose its beauty and peculiarities, and, at the same time, point out the possible occurrence of its puzzles. The Aharonov–Bohm effect constitutes a simple manifestation of Abelian gauge theory, while the Aharonov–Casher effect constitutes a simple manifestation of non-Abelian gauge theory. These two effects are published several decades ago, and remain among the building blocks of quantum mechanics ever since. The question of duality between the Aharonov–Casher and Aharonov–Bohm effects is raised by Hegen (1990), Bogachek and Landman (1994), Borunda et al. (2008), Rohrich (2010), and Vaidman (2012). A theoretical analysis relating the two effects is suggested in Avishai and Luck (2009). Paradoxes of the Aharonov–Bohm and the Aharonov–Casher effects are discussed by Vaidman (2013).

Both effects stress the essential role of phase of the wave functions (Berry, 1984). The Aharonov and Bohm effect involves the motions of charged particles (e.g., electrons) around but away from a region in which the magnetic field is finite. In the Aharonov and Casher effect (Aharonov and Casher, 1984), an electrical field is considered and its effect on particles with nonzero magnetic moment such as electrons (but also neutrons as they need not be charged) is analyzed. Both of these effects have direct relevance to condensed matter systems. Here we described these two effects and reviewed their relevance in condensed matter (mainly in mesoscopic systems).

In this short review, some aspects of the relevance of these effects to condensed matter physics are illuminated. In particular, we focus on the physics of mesoscopic systems, for which numerous experiments confirm the two effects. For the Aharonov–Bohm effect, examples of interference around a tube carrying magnetic flux, electrons on the ring (spectrum and persistent current) and an

interferometer are analyzed. For the Aharonov–Casher effect, examples of an interferometer, and an analysis of transmission and polarization in a two channel system are presented.

It is the authors' hope that the broad list of references will enable the readers to become acquainted with additional aspects of these effects in condensed matter physics.

Acknowledgments

The authors thank Tapash Chakraborty for suggesting this project, and Lev Vaidman for valuable comments.

Abstract

Miniaturization provides us with an intuitive way of understanding why, in the near future, quantum mechanics will become important for computation. The electronics industry for computers grows hand-in-hand with the decrease in size of integrated circuits. This miniaturization is necessary to increase computational power, that is, the number of floating-point operations per second (flops) a computer can perform. In the 1950s, electronic computers based on vacuum-tube technology were capable of performing approximately 10^3 floating-point operations per second, while nowadays (2022) there exist supercomputers whose power is greater than 100 petaflops (a 1 petaflops computer is capable of performing 10^{15} floating-point operations per second). This enormous growth of computational power has been made possible owing to progress in miniaturization, which may be quantified empirically in Moore's law. This law is the result of a remarkable observation made by Gordon Moore in 1965: the number of transistors on a single integrated-circuit chip doubles approximately every 18–24 months. This exponential growth has not yet saturated and Moore's law is still valid. At the present time the limit is close to 10^{10} transistors per chip and the typical size of circuit components is of the order of 5–10 nm. Extrapolating Moore's law, it is estimated that within a few years, one would reach the atomic size for storing a single bit of information. At that point, quantum effects will become unavoidably dominant.

Introduction

Miniaturization provides us with an intuitive way of understanding why, in the near future, quantum mechanics will become important for computation. The electronics industry for computers grows hand-in-hand with the decrease in size of integrated circuits. This miniaturization is necessary to increase computational power, that is, the number of floating-point operations per second (flops) a computer can perform. In the 1950s, electronic computers based on vacuum-tube technology were capable of performing approximately 10^3 floating-point operations per second, while nowadays (2022) there exist supercomputers whose power is greater than 100 petaflops (a 1 petaflops computer is capable of performing 10^{15} floating-point operations per second). This enormous growth of computational power has been made possible owing to progress in miniaturization, which may be quantified empirically in Moore's law. This law is the result of a remarkable observation made by Gordon Moore in 1965: the number of transistors on a single integrated-circuit chip doubles approximately every 18–24 months. This exponential growth has not yet saturated and Moore's law is still valid. At the present time the limit is close to 10^{10} transistors per chip and the typical size of circuit components is of the order of 5–10 nm. Extrapolating Moore's law, it is estimated that within a few years, one would reach the atomic size for storing a single bit of information. At that point, quantum effects will become unavoidably dominant.

[☆]Change History: September 2022. G. Benenti, G. Casati updated the chapter. Section "Simulating complex dynamics on actual quantum hardware" is newly added. Updated outlook.

Quantum physics sets fundamental limitations on the size of the circuit components. The first question under debate is whether it would be more convenient to push the silicon-based transistor to its physical limits or instead to develop alternative devices, such as quantum dots, single-electron transistors or molecular switches. A common feature of all these devices is that they are at the nanometer length scale, and therefore quantum effects play a crucial role.

So far, the quantum switches that could substitute silicon-based transistors and possibly be connected together to execute classical algorithms based on Boolean logic were discussed. In this perspective, quantum effects are simply unavoidable corrections that must be taken into account owing to the nanometer size of the switches. A quantum computer represents a radically different challenge: the aim is to build a machine based on quantum logic, that is, it processes the information and performs logic operations in agreement with the laws of quantum mechanics (Benenti et al., 2019).

Quantum logic

The elementary unit of quantum information is called a qubit (the quantum counterpart of the classical bit) and a quantum computer may be viewed as a many-qubit system. Physically, a qubit is a two-level system, like the two spin states of a spin-1/2 particle, the vertical and horizontal polarization states of a single photon or two levels of an atom.

A classical bit is a system that can exist in two distinct states, which are used to represent 0 and 1, that is, a single binary digit. The only possible operations (gates) in such a system are the identity ($0 \rightarrow 0, 1 \rightarrow 1$) and NOT ($0 \rightarrow 1, 1 \rightarrow 0$). In contrast, a quantum bit (qubit) is a two-level quantum system, described by a two-dimensional complex Hilbert space. In this space, one may choose a pair of normalized and mutually orthogonal quantum states, called $|0\rangle$ and $|1\rangle$ (say, the eigenstates of the Pauli operator σ_x), to represent the values 0 and 1 of a classical bit. These two states form a computational basis. From the superposition principle, any state of the qubit may be written as

$$|\Psi\rangle = \alpha|0\rangle + \beta|1\rangle, \quad (1)$$

where the amplitudes α and β are complex numbers, constrained by the normalization condition $|\alpha|^2 + |\beta|^2 = 1$.

A quantum computer can be seen as a collection of n qubits and therefore its wave function resides in a 2^n -dimensional complex Hilbert space. While the state of an n -bit classical computer is described in binary notation by an integer $k \in [0, 2^n - 1]$,

$$k = k_{n-1}2^{n-1} + \dots + k_1 2 + k_0, \quad (2)$$

with $k_0, k_1, \dots, k_{n-1} \in [0, 1]$ binary digits, the state of an n -qubit quantum computer is

$$\begin{aligned} |\Psi\rangle &= \sum_{k=0}^{2^n-1} c_k |k\rangle \\ &= \sum_{k_{n-1}, \dots, k_1, k_0=0}^1 c_{k_{n-1}, \dots, k_1, k_0} |k_{n-1} \dots k_1 k_0\rangle, \end{aligned} \quad (3)$$

where $|k_{n-1} \dots k_1 k_0\rangle \equiv |k_{n-1}\rangle \otimes \dots \otimes |k_1\rangle \otimes |k_0\rangle$. Notice that the complex numbers c_k are constrained by the normalization condition $\sum_{k=0}^{2^n-1} |c_k|^2 = 1$.

The superposition principle is clearly visible in Eq. (3): while n classical bits can store only a single integer k , the n -qubit quantum register can be prepared in the corresponding state $|k\rangle$ of the computational basis, but also in a superposition. The number of states of the computational basis in this superposition can be as large as 2^n , which grows exponentially with the number of qubits. The superposition principle opens up new possibilities for computation. When one performs a computation on a classical computer, different inputs require separate runs. In contrast, a quantum computer can perform a computation for exponentially many inputs on a single run. This huge parallelism is the basis of the power of quantum computation.

The superposition principle is not a uniquely quantum feature. Indeed, classical waves satisfying the superposition principle do exist. For instance, consider the wave equation for a vibrating string with fixed endpoints. Its solutions $|\varphi_k\rangle$ satisfy the superposition principle and one can write the most general state $|\varphi\rangle$ of a vibrating string as a linear superposition of these solutions, analogously to Eq. (3): $|\varphi\rangle = \sum_{k=0}^{2^n-1} c_k |\varphi_k\rangle$. It is therefore also important to point out the importance of entanglement for the power of quantum computation, as compared to any classical computation. Entanglement is the most spectacular and counter-intuitive manifestation of quantum mechanics, observed in composite quantum systems: it signifies the existence of non-local correlations between measurements performed on well-separated particles. After two classical systems have interacted, they are in well-defined individual states. In contrast, after two quantum particles have interacted, in general, they can no longer be described independently of each other. There will be purely quantum correlations between two such particles, independently of their spatial separation. Examples of two-qubit entangled state are the four states of the so-called Bell basis, $|\phi^\pm\rangle = \frac{1}{\sqrt{2}}(|00\rangle \pm |11\rangle)$ and $|\varphi^\pm\rangle = \frac{1}{\sqrt{2}}(|01\rangle \pm |10\rangle)$. The measure of the polarization state of one qubit will instantaneously affect the state of the other qubit, whatever their distance is. There is no entanglement in classical physics. Therefore, in order to represent the superposition of $N = 2^n$ levels by means of classical waves, these levels must belong to the same system. Indeed, classical states of separate systems can never be superposed. Thus, any computation based on classical waves requires a number N of levels that grows exponentially with n . If Δ is the typical energy separation between two consecutive levels, the amount of energy required for this computation is given by $\Delta 2^n$. Hence, the amount of physical resources needed for the computation grows exponentially with n . In contrast, due to entanglement, in quantum physics a general superposition of 2^n levels may be represented by means of n qubits. Thus, the amount of physical resources (energy) grows only linearly with n .

To implement a quantum computation, one must be able to control the evolution in time of the many-qubit state describing the quantum computer. As far as the coupling to the environment may be neglected, this evolution is unitary and governed by the

Schrödinger equation. It is well known that a small set of elementary logic gates allows the implementation of any complex computation on a classical computer. This is very important: it means that, when one changes the problem, one does not need to modify one's computer hardware. Fortunately, the same property remains valid for a quantum computer. It turns out that, in the quantum circuit model, any whatever complex unitary transformation acting on a many-qubit system can be decomposed into quantum gates acting on a single qubit and a suitable quantum gate acting on two qubits. Any unitary operation on a single qubit can be constructed using only Hadamard and phase-shift gates. The Hadamard gate is defined as follows: it turns $|0\rangle$ into $(|0\rangle + |1\rangle)/\sqrt{2}$ and $|1\rangle$ into $(|0\rangle - |1\rangle)/\sqrt{2}$. The phase-shift gate (of phase δ) turns $|0\rangle$ into $|0\rangle$ and $|1\rangle$ into $e^{i\delta}|1\rangle$. One can decompose a generic unitary transformation acting on a many-qubit state into a sequence of Hadamard, phase-shift and CNOT gates, where CNOT is a two-qubit gate, defined as follows: it turns $|00\rangle$ into $|00\rangle$, $|01\rangle$ into $|01\rangle$, $|10\rangle$ into $|11\rangle$, and $|11\rangle$ into $|10\rangle$. As in the classical XOR gate, the CNOT gate flips the state of the second (target) qubit if the first (control) qubit is in the state $|1\rangle$ and does nothing if the first qubit is in the state $|0\rangle$. Of course, the CNOT gate, in contrast to the classical XOR gate, can also be applied to any superposition of the computational basis states.

The decomposition of a generic unitary transformation of a n -qubit system into elementary quantum gates is in general inefficient, that is, it requires a number of gates exponentially large in n (more precisely, $O(n^{2^{2^n}})$ quantum gates). However, there are special unitary transformations that can be computed efficiently in the quantum circuit model, namely by means of a number of elementary gates polynomial in n . A very important example is given by the quantum Fourier transform, mapping a generic n -qubit state $\sum_{k=0}^{2^n-1} a_k |k\rangle$ into $\sum_{l=0}^{2^n-1} b_l |l\rangle$, where the vector $\{b_0, \dots, b_{N-1}\}$ is the discrete Fourier transform of the vector $\{a_0, \dots, a_{N-1}\}$, that is, $b_l = \sum_{k=0}^{N-1} e^{2\pi i k l / 2^n} a_k$. It can be shown that this transformation can be efficiently implemented in $O(n^2)$ elementary quantum gates, whereas the best known classical algorithm to simulate the Fourier transform, the fast Fourier transform, requires $O(n2^n)$ elementary operations. The quantum Fourier transform is an essential subroutine in many quantum algorithms.

Quantum algorithms

As shown above, the power of quantum computation is due to the inherent quantum parallelism associated with the superposition principle. In simple terms, a quantum computer can process a large number of classical inputs in a single run. For instance, starting from the input state $\sum_{k=0}^{2^n-1} c_k |k\rangle \otimes |0 \dots 0\rangle$, one may obtain the output state.

$$\sum_{k=0}^{2^n-1} c_k |k\rangle \otimes |f(k)\rangle. \quad (4)$$

Therefore, the function $f(k)$ is computed for all k in a single run (note that one needs two quantum registers to compute by means of a reversible unitary transformation $f(k)$; the second register requires enough qubits to load the output $f(k)$ for all input values $k = 0, 1, \dots, 2^n$, with n number of qubits in the first register). However, it is not an easy task to extract useful information from the output state. The problem is that this information is, in a sense, hidden. Any quantum computation ends up with a projective measurement in the computational basis: the qubit polarization is measured along the z -axis for all the qubits. The output of the measurement process is inherently probabilistic and the probabilities of the different possible outputs are set by the basic postulates of quantum mechanics. Given the state (4), one obtains $|\bar{k}\rangle |f(\bar{k})\rangle$ with probability $|c_{\bar{k}}|^2$, hence, the evaluation of the function $f(k)$ for a single $k = \bar{k}$, exactly as with a classical computer. However, there exist quantum algorithms that exploit quantum interference to efficiently extract useful information.

In 1994, Peter Shor proposed a quantum algorithm that efficiently solves the prime-factorization problem: given a composite odd positive integer N , find its prime factors. This is a central problem in computer science and it is conjectured, though not proven, that for a classical computer it is computationally difficult to find the prime factors. Indeed, the best classical algorithm, the number field sieve, requires $\exp(O(n^{1/3}(\log n)^{2/3}))$ operations. Shor's algorithm instead efficiently solves the integer factorization problem in $O((n^2 \log n \log \log n))$ elementary quantum gates, where $n = \log N$ is the number of bits necessary to code the input N . Therefore it provides an exponential improvement in speed with respect to any known classical algorithm. The integer factoring problem can be reduced to the problem of finding the period of the function $f(k) = a^k \bmod N$, where N is the number to be factorized and $a < N$ is chosen randomly. The modular exponentiation can be computed efficiently on a quantum computer and, starting from the state $\frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} |k\rangle |0 \dots 0\rangle$ (the equal superposition of all basis states in the first register can be obtained by applying one Hadamard gate for each qubit), one arrives at $\frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} |k\rangle |f(k)\rangle$. Notice that there are two quantum registers, the first one stores k , the second $f(k)$. By measuring the second register, one obtains the outcome $f(\bar{k})$. Thus, the quantum computer wave function collapses onto $\frac{1}{\sqrt{m}} \sum_{j=0}^{m-1} |\bar{k} + jr\rangle |f(\bar{k})\rangle$, where m is the number of k values such that $f(k) = f(\bar{k})$, and r is the period of $f(k)$, that is $f(k) = f(k + r)$. To determine the period r , one has to perform the quantum Fourier transform of the first register. The resulting wave function is peaked around integer multiples of N/r . From the measurement of this state, one can extract the period r . It is worth mentioning that there are cryptographic systems, such as RSA, that are used extensively today and that are based on the conjecture that no efficient algorithms exist for solving the prime factorization problem. Hence Shor's algorithm, if implemented on a large scale quantum computer, would break the RSA cryptosystem.

Other quantum algorithms have been developed. In particular, Grover has shown that quantum computers can also be useful for solving the problem of searching for a marked item in an unstructured database of $N = 2^n$ items. The best one can do with a classical computer is to go through the database, until one finds the solution. This requires $O(N)$ operations. In contrast, the same problem can be solved by a quantum computer in $O(\sqrt{N})$ operations. In this case, the gain with respect to classical computation is quadratic.

Quantum simulation of physical systems

The simulation of quantum many-body problems on a classical computer is a difficult task as the size of the Hilbert space grows exponentially with the number of particles. For instance, if one wishes to simulate a chain of n spin-1/2 particles, the size of the Hilbert space is 2^n . Namely, the state of this system is determined by 2^n complex numbers. As observed by Feynman in the 1980s, the growth in memory requirement is only linear on a quantum computer, which is itself a many-body quantum system. For example, to simulate n spin-1/2 particles one only needs n qubits. Therefore, a quantum computer operating with only a few tens of qubits can outperform a classical computer. Of course, this is only true if one can find an efficient quantum algorithm and if one can efficiently extract useful information from the quantum computer. Quite interestingly, a quantum computer can outperform a classical computer not only for the investigation of the properties of many-body quantum systems, but also for the study of the quantum and classical dynamics of complex single-particle systems.

For a concrete example, consider the quantum-mechanical motion of a particle in one dimension (the extension to higher dimensions is straightforward). It is governed by the Schrödinger equation

$$i\hbar \frac{d}{dt} \Psi(x, t) = H \Psi(x, t), \quad (5)$$

where the Hamiltonian H is given by

$$H = H_0 + V(x, t) = -\frac{\hbar^2}{2m} \frac{d^2}{dx^2} + V(x, t). \quad (6)$$

The Hamiltonian $H_0 = -(\hbar^2/2m)d^2/dx^2$ governs the free motion of the particle, while $V(x, t)$ is a (possibly time-dependent) one-dimensional potential. To solve Eq. (5) on a quantum computer with finite resources (a finite number of qubits and a finite sequence of quantum gates), one must first of all discretize the continuous variables x and t . If the motion essentially takes place inside a finite region, say $-d \leq x \leq d$, decompose this region into 2^n intervals of length $\Delta = 2d/2^n$ and represent these intervals by means of the Hilbert space of an n -qubit quantum register (this means that the discretization step drops exponentially with the number of qubits). Hence, the wave function $|\Psi(t)\rangle$ is approximated as follows:

$$|\tilde{\Psi}(t)\rangle = \frac{1}{N} \sum_{i=0}^{2^n-1} \Psi(x_i, t) |i\rangle, \quad (7)$$

where $x_i \equiv -d + (i + \frac{1}{2})\Delta$, $|i\rangle = |i_{n-1}\rangle \otimes \cdots \otimes |i_0\rangle$ is a state of the computational basis of the n -qubit quantum register and $N \equiv \sqrt{\sum_{i=0}^{2^n-1} |\Psi(x_i, t)|^2}$ is a factor that ensures correct normalization of the wave function. It is intuitive that $|\tilde{\Psi}\rangle$ provides a good approximation to $|\Psi\rangle$ when the discretization step Δ is much smaller than the shortest length scale relevant for the motion of the system. The Schrödinger Eq. (5) may be integrated by propagating the initial wave function $\Psi(x, 0)$ for each time-step ε as follows:

$$\Psi(xt + \varepsilon) = \mathcal{T} e^{-\frac{i}{\hbar}[H_0 + V(xt)]\varepsilon} \Psi(xt), \quad (8)$$

where $\mathcal{T}$ is the time-ordering operator. If the time-step ε is small enough, it is possible to write the Trotter decomposition

$$e^{-\frac{i}{\hbar}[H_0 + V(x, t)]\varepsilon} \approx e^{-\frac{i}{\hbar}H_0\varepsilon} e^{-\frac{i}{\hbar}V(x, t)\varepsilon}, \quad (9)$$

which is exact up to terms of order ε^2 . The operator on the right-hand side of Eq. (9) is still unitary, simpler than that on the left-hand side, and, in many interesting physical problems, can be efficiently implemented on a quantum computer. Advantage is taken of the fact that the Fourier transform can be efficiently preformed by a quantum computer. One can then write the first operator in the right-hand side of (9) as

$$e^{-\frac{i}{\hbar}H_0\varepsilon} = F^{-1} e^{+\frac{i}{\hbar}\left(\frac{\hbar^2 k^2}{2m}\right)\varepsilon} F, \quad (10)$$

where k is the variable conjugated to x and F the discrete Fourier transform. This represents a transformation from the x -representation to the k -representation, in which this operator is diagonal. Then, using the inverse Fourier transform F^{-1} , one returns to the x -representation, in which the operator $\exp(-iV(x, t)\varepsilon/\hbar)$ is diagonal. The wave function $\Psi(x, t)$ at time $t = l\varepsilon$ is obtained from the initial wave function $\Psi(x, 0)$ by applying l times the unitary operator.

$$F^{-1} e^{+\frac{i}{\hbar}\left(\frac{\hbar^2 k^2}{2m}\right)\varepsilon} F e^{-\frac{i}{\hbar}V(x, t)\varepsilon}. \quad (11)$$

Therefore, simulation of the Schrödinger equation is now reduced to the implementation of the Fourier transform plus diagonal operators of the form where c is some real constant. Note that an operator of the form

$$|x\rangle \rightarrow e^{icf(x)} |x\rangle, \quad (12)$$

where c is some real constant. Note that an operator of the form (12) appears both in the computation of $\exp(-iV(x, t)\varepsilon/\hbar)$ and of $\exp(-iH_0\varepsilon/\hbar)$, when this latter operator is written in the k -representation. The quantum computation of (12) is possible, using an ancillary quantum register $|y\rangle_a$, by means of the following steps:

$$|0\rangle_a \otimes |x\rangle \rightarrow |f(x)\rangle_a \otimes |x\rangle \rightarrow e^{icf(x)} |f(x)\rangle_a \otimes |x\rangle \rightarrow e^{icf(x)} |0\rangle_a \otimes |x\rangle = |0\rangle_a \otimes e^{icf(x)} |x\rangle. \quad (13)$$

The first step is a standard function evaluation and may be implemented by means of $O(n2^n)$ elementary quantum gates. Of course, more efficient implementations (polynomial in n) are possible when the function $f(x)$ has some structure, as it is the case for the potentials $V(x, t)$ usually considered in quantum-mechanical problems. The second step in (13) is the transformation $|y\rangle_a \rightarrow e^{icy} |y\rangle_a$ and can be performed in m single-qubit phase-shift gates, m being the number of qubits in the ancillary register. Indeed, one may write the binary decomposition of an integer $y \in [0, 2^n - 1]$ as $y = \sum_{j=0}^{m-1} \gamma_j 2^j$, with $\gamma_j \in \{0, 1\}$. Therefore,

$$\exp(iy) = \exp\left(\sum_{j=0}^{m-1} i\gamma_j 2^j\right) = \prod_{j=0}^{m-1} \exp(i\gamma_j 2^j), \quad (14)$$

which is the product of m single-qubit gates, each acting non-trivially (differently from identity) only on a single qubit. The j -th gate operates the transformation $|y_j\rangle_a \rightarrow \exp(i\gamma_j 2^j) |y_j\rangle_a$, with $|y_j\rangle_a \in \{|0\rangle, |1\rangle\}$ vectors of the computational basis for the j -th ancillary qubit. The third step in (13) is just the reverse of the first and may be implemented by the same array of gates as the first but applied in the reverse order. After this step the ancillary qubits are returned to their standard configuration $|0\rangle_a$ and it is therefore possible to use the same ancillary qubits for every time-step. Note that the number of ancillary qubits m determines the resolution in the computation of the diagonal operator (12). Indeed, the function $f(x)$ appearing in (12) is discretized and can take 2^m different values.

An example of an interesting dynamical model that can be simulated efficiently (and without ancillary qubits) on a quantum computer is the so-called quantum sawtooth map. This map represents the dynamics of a periodically driven system and is derived from the Hamiltonian

$$H(\theta, I; \tau) = \frac{I^2}{2} + V(\theta) \sum_{j=-\infty}^{+\infty} \delta(\tau - jT), \quad (15)$$

where (I, θ) are conjugate action-angle variables ($0 \leq \theta < 2\pi$), with the usual quantization rules, $\theta \rightarrow \theta$ and $I \rightarrow I = -i\partial/\partial\theta$ (set $\hbar = 1$) and $V(\theta) = -k(\theta - \pi)^2/2$. This Hamiltonian is the sum of two terms, $H(\theta, I; \tau) = H_0(I) + U(\theta; \tau)$, where $H_0(I) = I^2/2$ is just the kinetic energy of a free rotator (a particle moving on a circle parametrized by the coordinate θ), while $U(\theta; \tau) = V(\theta) \sum_j \delta(\tau - jT)$ represents a force acting on the particle that is switched on and off instantaneously at time intervals T . Therefore, it is said that the dynamics described by Hamiltonian (15) is kicked. The (quantum) evolution from time tT^- (prior to the t -th kick) to time $(t+1)T^-$ (prior to the $(t+1)$ -th kick) is described by a unitary operator U acting on the wave function Ψ :

$$\begin{aligned} \Psi_{t+1} &= U \Psi_t = U_T U_k \Psi_t; \\ U_T &= e^{-iT^2/2}, U_k = e^{ik(\theta - \pi)^2/2}. \end{aligned} \quad (16)$$

This map is called the quantum sawtooth map, since the force $F(\theta) = -dV(\theta)/d\theta = k(\theta - \pi)$ has a sawtooth shape, with a discontinuity at $\theta = 0$.

In the following, an exponentially efficient quantum algorithm for simulation of the map (16) is described. It is based on the forward/backward quantum Fourier transform between action and angle bases. Such an approach is convenient since the operator U is the product of the two operators U_k and U_T , which are diagonal in the θ and I representations, respectively. This quantum algorithm requires the following steps for one map iteration:

1. Apply U_k to the wave function $\Psi(\theta)$. In order to decompose the operator U_k into one- and two-qubit gates, we first of all write θ in binary notation:

$$\theta = 2\pi \sum_{j=1}^n \alpha_j 2^{-j}, \quad (17)$$

with $\alpha_j \in \{0, 1\}$. Here n is the number of qubits, so that the total number of levels in the quantum sawtooth map is $N = 2^n$. One can insert (17) into the unitary operator U_k , obtaining the decomposition

$$e^{ik(\theta - \pi)^2/2} = \prod_{i,j=1}^n e^{i2\pi^2 k \left(\alpha_i 2^{-i} - \frac{1}{2n} \right) \left(\alpha_j 2^{-j} - \frac{1}{2n} \right)}, \quad (18)$$

which is the product of n^2 two-qubit gates, each acting non-trivially only on the 4-dimensional subspace spanned by the qubits i and j .

2. The change from the θ to the I representation is obtained by means of the quantum Fourier transform, which requires and $\frac{1}{2}n(n+1)$ elementary quantum gates.
3. In the I representation, the operator U_T has essentially the same form as the operator U_k in the θ representation, and therefore it can be decomposed into n^2 two-qubit gates, similarly to Eq. (18).
4. Return to the initial θ representation by application of the inverse quantum Fourier transform.

Thus, overall, this quantum algorithm requires $3n^2 + n$ gates per map iteration. This number is to be compared with the $O(n2^n)$ operations required by a classical computer to simulate one map iteration by means of a fast Fourier transform. Thus, the quantum simulation of the quantum sawtooth map dynamics is exponentially faster than any known classical algorithm. Note that the

resources required to the quantum computer to simulate the evolution of the sawtooth map are only logarithmic in the Hilbert space dimension N .

As an example of the efficiency of this quantum algorithm, Fig. 1 shows the Husimi functions, taken after 1000 map iterations. It is noted that $n = 9$ qubits are sufficient to observe the appearance of integrable islands, while at $n = 16$ these islands exhibit a complex hierarchical structure in the phase space.

However, there is an additional aspect to be taken into account. Any quantum algorithm has to address the problem of efficiently extracting useful information from the quantum computer wave function. Indeed, the result of the simulation of a quantum system is the wave function of this system, encoded in the n qubits of the quantum computer. The problem is that, in order to measure all $N = 2^n$ wave function coefficients by means of standard polarization measurements of the n qubits, one has to repeat the quantum simulation a number of times exponential in the number of qubits. This procedure would spoil any quantum algorithm, even in the case, like the present one, in which such algorithm could compute the wave function with an exponential gain with respect to any classical computation. Nevertheless, there are some important physical questions that can be answered in an efficient way.

The quantum computation can provide an exponential gain (with respect to any known classical computation) in problems that require the simulation of dynamics up to a time t which is independent of the number of qubits. In this case, provided that one can extract the relevant information in a number of measurements polynomial in the number of qubits, one should compare, in the example of the quantum sawtooth map, $O(t(\log N)^2)$ elementary gates (quantum computation) with $O(tN \log N)$ elementary gates (classical computation). This is, for instance, the case of dynamical correlation functions of the form

$$C_t \equiv \langle \Psi_0 | A_t^\dagger B_0 | \Psi_0 \rangle = \langle \Psi_0 | (U^\dagger)^t A_0^\dagger U^t B_0 | \Psi_0 \rangle, \quad (19)$$

where U is the time-evolution operator (16) for the quantum sawtooth map. Similarly, one can efficiently compute the fidelity of quantum motion, which is a quantity of central interest in the study of the stability of quantum motion under perturbations. The fidelity $f(t)$ (also called the Loschmidt echo), measures the accuracy with which a quantum state can be recovered by inverting, at time t , the dynamics with a perturbed Hamiltonian. It is defined as

$$f(t) = \langle \Psi | (U_\epsilon^\dagger)^t U^t | \Psi \rangle = \langle \Psi | e^{iH_\epsilon t} e^{-iHt} | \Psi \rangle. \quad (20)$$

Here the wave vector $|\Psi\rangle$ evolves forward in time with Hamiltonian H up to time t and then evolves backward in time with a perturbed Hamiltonian H_ϵ . If the evolution operators U and U_ϵ can be simulated efficiently on a quantum computer, as is the case in many physically interesting situations, then the fidelity of quantum motion can be evaluated with exponential speed up with respect to known classical computations. As shown in Fig. 2, it is possible to measure the fidelity by means of a Ramsey-type quantum interferometer method. A single ancillary qubit is needed, initially prepared in the state $|0\rangle$, while the input state for the other n qubits is a given initial state $|\Psi_0\rangle$ for the quantum sawtooth map. Two Hadamard gates are applied to the ancillary qubit, and in between these operations a controlled- W operation is applied (W is a unitary operator), namely W is applied to the other n qubits only if the ancillary qubit is in its $|1\rangle$ state. As a result, one obtains the following final overall state for the $n + 1$ qubits:

$$\frac{1}{2} [(|0\rangle + |1\rangle)|\Psi_0\rangle + (|0\rangle - |1\rangle)W|\Psi_0\rangle]. \quad (21)$$

If $W = (U_\epsilon^\dagger)^t U^t$, then one can derive the fidelity from polarization measurements of the ancillary qubit. One obtains

Fig. 1 Husimi function for the sawtooth map for $n = 9$ (left) and $n = 16$ (right) qubits, in action angle variables (I, θ) , with $-N/2 \leq I < N/2$ (vertical axis, $N = 2^n$) and $0 \leq \theta < 2\pi$ (horizontal axis), averaged in the interval $950 \leq t \leq 1000$, for $T = 2\pi/N$ and $kT = -0.1$. An action eigenstate, $|\psi_0\rangle = |m_0\rangle$, with $m_0 = [0.38 N]$ is considered as initial state at time $t = 0$. The color is proportional to the density: blue for zero and red for maximal density. Fig. 2 Schematic drawing of a quantum circuit implementing a Ramsey-type quantum interferometer. The top line denotes a single ancillary qubit, the bottom line a set of n qubits, H the Hadamard gate and W a unitary transformation. Benenti G and Casati G (2016) Quantum computation of complex systems, in: Hashmi, S (ed.) *Reference Module in Materials Science and Materials Engineering*, United Kingdom: Elsevier Science.

$$f(t) = \langle \sigma_z \rangle^2 + \langle \sigma_y \rangle^2, \quad (22)$$

where $\langle \sigma_z \rangle$ and $\langle \sigma_y \rangle$ are the expectation values of the Pauli operators σ_z and σ_y . Provided that the quantum algorithm implementing U is efficient, as it is the case for the quantum sawtooth map, the fidelity can then be computed efficiently.

Simulating complex dynamics on actual quantum hardware

Present-day quantum computers, whether they are based on superconducting qubits or on trapped ions, suffer from significant decoherence and the effects of various noise sources. Therefore, achieving the quantum advantage in practically relevant problems such as chemical reactions, new materials design, or biological processes, is an imposing task. Note that quantum advantage is achieved when a quantum computer can solve a problem that no classical computer can solve in a feasible amount of time. The progress of currently available quantum processors can nevertheless be benchmarked by simulating complex dynamics.

An illustrative example is again provided by the quantum sawtooth map. The classical limit of such map is chaotic when $kT < -4$ or $kT > 0$. Although the sawtooth map is a deterministic system, in the chaotic regime the motion along the action direction is in practice indistinguishable from a random walk, with diffusion in the action variable. If one considers a classical ensemble of trajectories with fixed initial action m_0 and random initial angle θ , the second moment of the action distribution grows linearly with the number t of map iterations, $\langle (\Delta I)^2 \rangle \approx D(k)t$, with a diffusion coefficient D dependent on k . The quantum sawtooth map, in agreement with the correspondence principle, initially exhibits diffusive behavior, with the classical diffusion coefficient D . However, after a break time t^* , quantum interference leads to suppression of diffusion. For $t > t^*$, the quantum distribution reaches a steady state which decays exponentially over the action eigenbasis:

$$W_m \equiv |\langle m | \Psi \rangle|^2 \approx \frac{1}{\ell} \exp \left[-\frac{2|m - m_0|}{\ell} \right], \quad (23)$$

where the index m singles out the action eigenstates ($I|m\rangle = m|m\rangle$), the system is initially prepared in the eigenstate $|m_0\rangle$, and ℓ is known as the localization length of the system. Therefore, for $t > t^*$ only

$$\sqrt{\langle (\Delta I)^2 \rangle} \approx \sqrt{Dt^*} \approx \ell \quad (24)$$

levels are populated. This phenomenon, known as dynamical localization, is due to quantum interference effects, suppressing the underlying classical diffusion process after a time $t^* \approx \ell \approx D$.

Fig. 3 shows the results of a dynamical localization experiment with $n = 3$ qubits on a real and freely available IBM quantum processor, with superconducting qubits, remotely accessed through cloud quantum programming (Pizzamiglio et al., 2021). The initial condition is peaked in action, $\Psi_0(m) = \langle m | \Psi_0 \rangle = \delta_{m, m_0}$, with $m_0 = 0$. The quantum algorithm for the sawtooth map allows

Fig. 3 Dynamical localization in the quantum sawtooth map with $n = 3$ qubits, $kT = 1.5$, $k \approx 0.273$. Data from the IBM quantum processors *lima* (red) are obtained after averaging over 10 repetitions of 8192 experimental runs, and compared with the Qiskit simulator (blue) and the noiseless simulation (green). Pizzamiglio A, Chang SY, Bondani M, Montangero S, Gerace D and Benenti G (2021) Dynamical localization simulated on actual quantum hardware, *Entropy* 23: 654.

one to compute the wave vector $\Psi_i(m)$ as a function of the number of map steps, and then the probability distribution $W_i(m) = |\Psi_i(m)|^2$. In the figure $k \approx 0.273 < 1$, so that the distribution is already localized after a single map step. On the other hand, here $kT = 1.5$, corresponding to diffusive, chaotic behavior for the underlying classical dynamics. In Fig. 3 the ideal, noiseless distribution after $t = 1$ map step is compared with the results of the real quantum hardware and with a simulator (Qiskit, provided by IBM), which takes into account a few relevant noise sources, modeling in particular dephasing, relaxation, and readout errors. The results show that the quantum hardware exhibits a localization peak, which emerges from quantum interference. Note that the quantum algorithm performs forward-backward Fourier transform, thus exploring the entire Hilbert space of the quantum register in a complex multiple-path interferometer that leads to wave-function localization. As such, dynamical localization is a very fragile quantum phenomenon, extremely sensitive to noise. The height of the peak, is significantly smaller than the noiseless value and the prediction of the Qiskit simulator. These results show that the Qiskit simulator underestimates some of the relevant noise channels, such as fluctuations of the qubit quality parameters between calibrations of the quantum computer, memory effects, and cross-talks between qubits.

The presence of these noise channels also shows the imposing difficulties in scaling quantum algorithms to a large number of qubits and of quantum gates. On the other hand, striking progress has been reported in recent years, quantified for instance by the quantum volume V_Q , a single number meant to encapsulate the quantum computer performance, including number of available qubits and number of quantum gates that can be reliably implemented, before errors dominate (Cross et al., 2019). The quantum volume is defined as

$$\log_2 V_Q = \arg \max_{\kappa \leq n} \{ \min [\kappa, d(\kappa)] \}, \quad (25)$$

where n is the number of qubits in the quantum computer, and $d(\kappa) = 1/(\kappa \varepsilon_{\text{eff}}(\kappa))$, known as circuit depth, is determined by an effective error rate $\varepsilon_{\text{eff}}(\kappa)$ for a subset of $\kappa \leq n$ qubits, on which sequences of random two-qubit unitaries are implemented. From January 2020 to December 2021, the reported values of V_Q have increased from $V_Q = 32$ to $V_Q = 2048$ (for a comparison, data from Fig. 3 have been obtained with a machine with quantum volume $V_Q = 8$).

Conclusion

A few significant examples have been discussed showing the capabilities of a quantum computer in the simulation of complex physical systems. A quantum computer with a few tens of qubits and a long enough decoherence time to allow the implementation of a large number of quantum gates, would outperform a classical computer in this kind of problems.

Any practical implementation of a quantum computer has to face errors, due to the inevitable coupling of the computer to the surrounding environment or to imperfections in the quantum computer hardware. The first kind of error is known as decoherence and is a threat to the actual implementation of any quantum computation. More generally, decoherence theory has a fundamental interest beyond quantum information science, since it provides explanations for the emergence of classicality in a world governed by the laws of quantum mechanics (Zurek, 2003). The core of the problem is the superposition principle, according to which any superposition of quantum states is an acceptable quantum state. This entails consequences that are absurd according to classical intuition, like the superposition of “cat alive” and “cat dead” that is considered in the Schrödinger’s cat paradox. The interaction with the environment can destroy the coherence between the states appearing in a superposition (for instance, the “cat alive” and “cat dead” states). Therefore, decoherence invalidates the quantum superposition principle, which is at the heart of the power of quantum algorithms. The presence of device imperfections, although not leading to any decoherence, also hinders the implementation of any quantum computational task, introducing errors. Therefore, decoherence and imperfection effects appear to be the ultimate obstacle to the realization of a large-scale quantum computer.

Note that a quantum computer is not necessarily required for implementing quantum simulation. Simpler quantum devices, called (analog) quantum simulators can mimic the evolution of other quantum systems in an analog manner. Such simulators are problem-specific quantum machines, namely controllable quantum systems used to simulate other quantum systems (Georgescu et al., 2014).

At present (2022) it is not clear if and when a useful quantum computer, capable of outperforming existing classical computers in important computational tasks, will be built. In order to perform coherent controlled evolution of a many-qubit system, one needs to take into account the problem of decoherence, and therefore large-scale quantum computers appear unrealistic with present technology. On the other hand, progress in the field has been huge in recent years. Moreover, we should bear in mind that technological breakthroughs (such as the transistor was for the classical computer) are always possible and that no fundamental objections have been found against the possibility of building a quantum computer.

Abstract

The last 5 years have seen a dramatic evolution of platforms for quantum computing, taking the field from physics experiments to quantum hardware and software engineering. Nevertheless, despite this progress of quantum processors, the field is still in the noisy intermediate-scale quantum (NISQ) regime, seriously limiting the performance of software applications. Key issues involve how to achieve quantum advantage in useful applications for quantum optimization and materials science. In this article we will describe recent work to establish relevant benchmarks for quantum supremacy and quantum advantage, present recent work on applications of variational quantum algorithms for optimization and electronic structure determination, discuss how to achieve practical quantum advantage, and finally outline current work and ideas about how to scale up to competitive quantum systems.

Key points

- Progress of gate-based superconducting quantum processors
- Status of quantum supremacy and quantum advantage
- Quantum approximate optimization algorithm (QAOA) applied to flight logistics
- Variational quantum eigensolver (VQE) applied to molecular ground state energies
- Methods for quantum error mitigation in noisy quantum processors
- Prospects of useful quantum advantage in current efforts to scale up superconducting quantum processors
- Improved and alternative superconducting qubits and architectures
- Superconducting platforms for quantum simulation of fundamental and applied physics problems

Introduction

Since around 1980, quantum computing (QC) and quantum simulation (QS) have gone from fantasy to possibility, from concept to application, from basic science to engineering (Wendin, 2017; Gu et al., 2019; Krantz et al., 2019; Kjaergaard et al., 2020; Blais et al., 2020, 2021; Bruzewicz et al., 2019; Brown et al., 2021; Daley et al., 2022). In 2011, at a workshop at Benasque in the Spanish Pyrenees, at a memorable session we discussed in particular the future of QC. Myself, I predicted 20–30 years for useful applications, while Rainer Blatt emphasized that if we did not have any decisive results in 5 years, QC would soon be dead. It seems we were both right: QC did take off around 2016 at engineering levels, while really useful competitive applications showing practical quantum advantage may still be 10–20 years ahead. The intense discussions in the European quantum community then led to the 2016 Quantum Manifesto, and to the EU Quantum Flagship setting sail in 2018.

From 2019, the field has seen a huge development of platforms for QC and simulation with superconducting devices and systems (Arute et al., 2019; Wu et al., 2021; Zhu et al., 2022; Córcoles et al., 2020; Gambetta, 2022a), including experiments indicating quantum supremacy (Arute et al., 2019; Wu et al., 2021; Zhu et al., 2022), a concept introduced by Preskill (2012). However, we are living in the era of noisy intermediate-scale quantum (NISQ) devices (Preskill, 2018), and it is currently impossible to build superconducting quantum processing units (QPUs) where one can entangle more than 10–15 qubits with high probability during the coherence time. Which means there is no time for useful computation with deep quantum circuits, only time to characterize the device and demonstrate physical entanglement—impressive but not necessarily useful. Nevertheless, IBM is now scaling superconducting QPUs to more than 1000 qubits in 2023 and over 4000 qubits in 2025 (Gambetta, 2022a; Bravyi et al., 2022), aiming for seamless integration of high-performance computers (HPCs) and QPU accelerators. Google (Lucero, 2021) seems to focus on modest-size quantum error-corrected QPUs for large-scale quantum computational breakthroughs already by 2029, while at the same time there seems to be some consensus (Sanders et al., 2020; Babbush et al., 2021; Beverland et al., 2022) that practical quantum advantage may take much longer to achieve.

To create useful applications showing quantum advantage, it is necessary to scale up QPUs and related classical-quantum hybrid (HPC+QC) infrastructure. This explains a number of current trends: (i) stay at “small” scales (≤ 100 qubits) and try to solve coherence problems and create useful applications before scaling up; (ii) go for large scales (≥ 1000 qubits) and try to implement quantum error correction (QEC) for quantum advantage or superiority while scaling up; (iii) scale up and solve large-scale hardware (HW) and software (SW) integration at systems levels, waiting for practical quantum advantage for use cases to emerge.

The question of the feasibility of powerful quantum computers beating classical super-HPC hinges on that it will be ultimately possible to perform QEC. When John Martinis’ group announced that their superconducting quantum circuits were at the surface code threshold for fault tolerance (Barends et al., 2014), then the field opened up and went from quantum physics toward QC, scaling up HW and SW (Barends et al., 2015, 2016; Song et al., 2017; Kandala et al., 2017, 2019; Arute et al., 2019; Gong et al., 2019, 2021, 2022), and implementing significant quantum algorithms and quantum physics experiments (Barends et al., 2015, 2016; Kandala et al., 2017, 2019; Arute et al., 2020b, a; Neill et al., 2021; Gong et al., 2019, 2021, 2022; Zhang et al., 2022b; Mi et al., 2022b; Stanisic et al., 2022), including demonstrations of significant steps toward QEC (Andersen et al., 2020; Chen et al., 2021b; Marques et al., 2022; Krinner et al., 2022; Acharya et al., 2023).

Much of the current discussion concerns how to get from proofs of concept to useful applications. Consider the way QC is being promoted by Google (Lucero, 2021): “Within the decade, Google aims to build a useful, error-corrected quantum computer. This will accelerate solutions for some of the world’s most pressing problems, like sustainable energy and reduced emissions to feed the world’s growing population, and unlocking new scientific discoveries, like more helpful AI.”

This tells us that the world’s most pressing problems, like benchmarking climate models, are already subject to large-scale calculations, pushing super-HPCs to their limits set by NP-hard problems. The intended role of QPUs is to provide quantum superiority and to go far beyond those classical limits. However, in the short term, at least during this decade, this can only be achieved by experimental quantum co-processors running specific subroutines addressing classically hard problems, omnipresent in industrial use cases (QUTAC, 2021; Kim et al., 2022). In the short term, industry will effectively be co-developing quantum algorithms as subroutines, and benchmark them against competing classical algorithms. If this leads to quantum advantage already in the short term, that will be a great bonus. The important thing to understand is that lack of quantum advantage for now does not

jeopardize powerful computing—exascale super-HPC platforms will continue addressing the world’s most pressing problems, and eventually QPU accelerators may provide quantum leaps.

This perspective article can be looked upon as a self-contained second part of a research and review paper (Wendin, 2017) that stopped short at the beginning of the current engineering era of scaling up devices and building QC ecosystems. The purpose is to focus on addressing the quite dramatic development since then, trying to “predict the future” based on current visions, roadmaps, efforts, and investments that aim for the next 10 years (Alexeev et al., 2021; Altman et al., 2022; Ang et al., 2022), outlining a sustainable quantum evolution that hopefully survives the quantum hype (Ezratty, 2022; Das Sarma, 2022). To be able to do so in this brief article, we will frequently refer to Wendin (2017) and to recent reviews for basic background, technology, and methods. This review will focus on superconducting technology and systems based on circuit quantum electrodynamics (cQED) (Gu et al., 2019; Blais et al., 2021), but will also provide glimpses of the broader development.

Overview

Quantum processor systems: Hardware and software

With NISQ devices with limited coherence time, the necessary circuits are much too deep to achieve reasonable accuracy. It is therefore necessary to break up the quantum circuits in short, low-depth pieces with a small number of gates that can be run on QPUs during the coherence time. These often make use of variational quantum algorithms (VQAs) where one calculates the expectation value of a cost function, for example, a Hamiltonian, using a parameterized trial function. A classical HPC controls and executes the classical optimization loop: computes averages, searches for improved energies, computes new parameters, and updates the quantum circuit.

Fig. 1 illustrates the basics of QC from a user perspective. The program code is typically prepared on a small classical computer and then submitted to the application programming interface (API) of an HPC frontend. The HPC interprets the quantum part and prepares the code defining the quantum circuit. This is finally loaded into the stack of the QPU. In the case of an ideal QPU, the code is executed on the QPU until solution is achieved, and the results finally read out and sent back to the HPC for postprocessing. In the NISQ world of QPUs, the quantum execution has to be limited to low-depth (shallow) quantum circuits that can be executed within the coherence time. This necessitates repeated quantum-classical processing loops for optimization of variational problems.

Here the classical computer is a bottleneck. The HPC calculation takes much longer time than the QPU execution time, even if the HPC responds without delay (no latency) and the QPU backend is available immediately on request. This is hybrid HPC+QC computation, and is algorithm dependent.

Quantum advantage in the NISQ era depends critically on efficient representation and coding of problems. There is a distinct difference between binary decision and optimization problems that can be mapped directly on qubits, and electron structure problems that need additional extensive transformations from fermionic operators to qubits.

Quantum algorithms

An ideal digital quantum computer executes perfect gates on ideal qubits with infinite coherence time. It evolves the time-evolution operator e^{-iHt} corresponding to a given Hamiltonian describing the problem (see e.g., Wendin, 2017). e^{-iHt} is then broken down

Fig. 1 HPC + QC. The user prepares a program and submits it to the classical frontend. The HPC prepares the quantum circuit and sends it to the QC. The HPC/QC registers have N bits/qubits, that is, $n = 2^N$ possible configurations/states. The HPC register can only be in one of 2^N states: $|00 \dots 00\rangle, |00 \dots 01\rangle, |00 \dots 10\rangle, \dots |11 \dots 11\rangle$ at each instance of time t , while the QC register can be in a *superposition of all states*: $f_1(t)|00 \dots 00\rangle + f_2(t)|00 \dots 01\rangle + f_3(t)|00 \dots 10\rangle, \dots + f_{n-1}(t)|11 \dots 10\rangle + f_n(t)|11 \dots 11\rangle$. This describes *time-dependent quantum superposition and entanglement* and can, at best, lead to exponential quantum advantage (EQA).

into a product of factors for the different terms of the Hamiltonian. These factors are finally represented in terms of products of quantum gates constituting a quantum circuit. In this case, the role of a classical computer is exclusively pre- and post-processing: preprocessing to construct the quantum circuit and postprocessing to read out and treat the results. Both of these are in principle NP-hard. To get desired results, the QC must be able to run for sufficiently long times to execute deep quantum circuits, which requires perfect qubits and gates. With NISQ devices, it is not possible to run phase-estimation algorithms (PEAs) to compute the energies of molecules—the needed quantum circuits are far too long with respect to the coherence time. This has led to alternative approaches, calculating the expectation value of the problem Hamiltonian with respect to parametrized trial functions and then optimizing the parameters for lowest energy.

VQAs are generally based on constructing parametrized trial functions to compute and minimize the expectation value of a cost function. In the quantum case, the specific quantum computation involves computing the expectation value of a Hamiltonian cost function, while the classical computer prepares the trial function, computes the energy, updates the trial function parameters and minimizes the energy in an optimization loop. Extensive discussions and reviews of quantum methods and algorithms are presented by Wang et al. (2019), Cerezo et al. (2021), Franca and Garcia-Patron (2021), Tilly et al. (2022), Bharti et al. (2022), Abhijith et al. (2022), and Kowalsky et al. (2022).

Quantum supremacy

John Preskill was the first one to explicitly introduce the concept of quantum supremacy in a 2012 paper discussing QC and the entanglement frontier (Preskill, 2012). In 2016, Boixo et al. then described how to characterize quantum supremacy in near-term devices (Boixo et al., 2018) preparing for the 2019 Google experiment to demonstrate quantum supremacy (Arute et al., 2019). The idea was to measure the output of a pseudo-random quantum circuit (Fig. 2) to produce a distribution of samples, and to compute the cross-entropy describing the “overlap” between the quantum and classical distributions (see Hangleiter and Eisert (2022) for a review of quantum random sampling).

Aaronson and Chen (2017) put this on complexity-theoretic foundations. They noted that for the sampling tasks, not only simulation but also verification might need classical exponential time. This made it advantageous to directly consider the probability of observed bitstrings, rather than the distribution of sampled bitstrings. To this end, Aaronson and Chen (2017) showed that there is a natural average-case hardness assumption (Heavy Output Generation, HOG), which has nothing to do with sampling, yet implies that no polynomial-time classical algorithm can pass a statistical test passed by the outputs of the quantum sampling procedure. The quantum volume benchmark of IBM (see Section “Quantum volume—QV”) is based on HOG.

As mentioned, Google based their quantum supremacy demonstration (Arute et al., 2019) on sampling quantum and classical distributions, calculating the cross-entropy as described by Boixo et al. (2018). Cross-entropy benchmarking (XEB) has the advantage that it provides deeper insight than HOG, including measures of fidelity, and allows tracing of the development from small processors to devices that can only be simulated approximately.

The Google paper (Arute et al., 2019) stated that an HPC would take 10,000 years. That statement immediately met with a rebuttal on the IBM Research blog by Pednault et al. (2019), explaining that an ideal simulation of the same task in a conservative, worst-case estimate could be performed on a classical system in 2.5 days and with far greater fidelity. Therefore the quantum supremacy threshold had not been met by Google using 53 qubits.

This was of course valid criticism, but effectively just delaying the inevitable. An experiment that more decisively passed the quantum supremacy threshold was soon announced by Chinese researchers (Wu et al., 2021; Zhu et al., 2022) using the Zuchongzhi processor, closely following Google’s recipes, to demonstrate distinct quantum computational advantage. In the most recent experiment (Zhu et al., 2022) using 60-qubit 24-cycle random circuit sampling (RCS), the state-of-the-art HPC classical

Fig. 2 Control operations for generating the pseudo-random quantum circuits for Google’s quantum supremacy benchmarking protocol. Adapted from Arute F, et al. (2019) Quantum supremacy using a programmable superconducting processor. Nature 574: 505–510.

simulation would have taken tens of thousands of years, while Zuchongzhi 2.1 only took about 4.2 h, thereby significantly enhancing the quantum computational advantage.

As emphasized by Pednault et al. (2019), quantum supremacy is a threshold that does not automatically certify the quantum processor to be useful for running useful algorithms. However, it does benchmark the quality of the processor. The original Google experiment used a 53-qubit quantum processor that implements a large two-qubit gate quantum circuit of depth 20, with 430 two-qubit and 1,113 single-qubit gates, and with predicted total fidelity of $F_{XEB} = 0.2\% > 0$. The condition for quantum supremacy, $F_{XEB} > 0$, is based on statistics of creating an ensemble of a million runs of quantum circuits. The problem is that to solve, for example, a quantum chemistry problem based on 53 qubits, the depth of the quantum circuit would have to be in the range of a million. To solve useful problems challenging HPCs one must be able to run perfect quantum circuits with depth much larger than the circuit width, involving a very large number of 2-qubit gates. The name of the game is how to achieve practical quantum advantage.

Performance metrics

Cross entropy benchmarking—XEB

The task is to sample the 2^N bitstring output of a pseudo-random quantum circuit (Fig. 2). XEB compares the probability for observing a bitstring experimentally with the corresponding ideal probability computed via simulation on a classical computer.

For a given circuit, one collects the measured bitstring sample $\{x_i\}$ and computes the linear XEB fidelity (Arute et al., 2019)

$$F_{XEB} = 2^N \langle P(x_i) \rangle_i - 1 \quad (1)$$

where N is the number of qubits, $P(x_i)$ is the probability of the *experimental* bitstring $\{x_i\}$ computed for the *ideal quantum circuit*, and the average is over the observed bitstrings. F_{XEB} is correlated with how often one samples high-probability bitstrings. If the distribution is uniform, then $\langle P(x_i) \rangle_i = 1/2^N$ and $F_{XEB} = 0$. Values of F_{XEB} between 0 and 1 correspond to the probability that no error has occurred while running the circuit. In the Google case (Arute et al., 2019), the computed values are very small, $F_{XEB} \sim 10^{-3}$. This may represent proof of principle, but hardly provides any useful result. One needs to have $F_{XEB} \sim 1$ to be able to run algorithms, useful or not.

To demonstrate quantum supremacy, one must achieve a high enough F_{XEB} for a circuit with sufficient width and depth such that the classical computing cost of $P(x_i)$ for the full circuit is intractable. $P(x_i)$ must be calculated classically by simulating the ideal quantum circuit, which is formally intractable in the region of quantum supremacy. Since 2016, or even before, it has been understood that RCS, the task to sample the 2^N bitstring output of a pseudo-random quantum circuit, will not scale to arbitrarily many qubits without error correction (Aaronson and Chen, 2017). Bouland et al. (2019) provided strong complexity theoretic evidence of classical hardness of RCS, placing it on par with the best theoretical proposals for supremacy. However, very recently Aharonov et al. (2022) (see also Brubaker, 2023) produced a polynomial time classical algorithm for sampling from the output distribution of a noisy random quantum circuit. This gives strong evidence that, in the presence of a constant rate of noise per gate, RCS cannot be the basis of a *scalable* experimental violation of the extended Church-Turing thesis. Noise kills entanglement and makes RCS classically tractable (provided the HPC has enough memory to do the calculation).

However, the algorithm does not directly address finite-size RCS-based quantum supremacy experiments (Aharonov et al., 2022), so the result is not directly applicable to current attempts to invalidate the quantum supremacy results (Arute et al., 2019; Wu et al., 2021; Zhu et al., 2022) using classical HPC. Pan et al. (2022) solved the Google sampling problem classically in about 15 h on a computational cluster with 512 GPUs with state fidelity 0.0037 (Google 0.00224), and claimed that it would only take few dozen seconds on an exascale machine, much faster than Google.

Clearly it provides some satisfaction to demonstrate in practice that an HPC can beat the noisy 53q Sycamore QPU. However, a more challenging target for the HPC may now be to beat the 66q Zuchongzhi 2.1 with its 60-qubit 24-cycle RCS (Zhu et al., 2022).

Quantum volume—QV

The fundamental challenges in the NISQ era can be illustrated using the concept of quantum volume (QV) introduced by IBM (Cross et al., 2019). QV is linked to system error rates, and quantifies the largest random circuit of equal width and depth that a specific computer can successfully implement given decoherence, gate fidelities, connectivity, and more (Cross et al., 2019; Pelofske et al., 2022).

QV is a benchmarking protocol based on the execution of a pseudo-random quantum circuit with a fixed but generic form producing a bitstring $\{x\}$ (Fig. 3). QV quantifies the largest random circuit U of equal width N (number of qubits) and depth d (number of layers) that the computer successfully implements $U = U(d), \dots, U(2)U(1)$ and produces the ideal output distribution $p_U(x) = |\langle x|U|0 \rangle|^2$ where $\{x\}$ is an observable bit string.

Benchmarking the QV, one runs circuits with an increasing number of cycles $d = 1, \dots, d_{max}$ with $d = N$, and measures the success rate for increasing the depth d until one reaches a prescribed success threshold. To define when a model circuit U has been successfully implemented in practice, Cross et al. (2019) use the HOG problem formulated by Aaronson and Chen (2017): “Given as input a random quantum circuit C (drawn from some suitable ensemble), generate output strings $x_1, \dots, x_k$, at least a $2/3$ fraction of which have greater than the median probability in C ’s output distribution.” This means that the set of output probabilities $p_U(x)$ are sorted in ascending order of probability, and the heavy (high probability) output generation problem is to produce a set of output strings $\{x\}$ such that more than two-thirds are heavy, that is, greater than the median probability.

Fig. 3 IBM QV pseudo-random quantum circuit (Cross et al., 2019) consisting of d layers (depth) of random permutations π of the N qubit labels, followed by random $SU(4)$ two-qubit gates. When the circuit width N is odd, one of the qubits is idle in each layer. From Cross AW, Bishop LS, Sheldon, S, Nation, PD, Gambetta, JM, (2019) Validating quantum computers using randomized model circuits. *Physical Review A* 100: 032328.

Aaronson and Chen (2017) state: “HOG is easy to solve on a quantum computer, with overwhelming success probability, by the obvious strategy of just running C over and over and collecting k of its outputs,” and demonstrate that HOG is exponentially hard for a classical computer. The important thing is that the approach makes no reference to sampling or relation problems. Thus, one can shift focus from sampling algorithms to algorithms that simply estimate amplitudes.

Pelofske et al. (2022) recently published a guide to the QV: “Quantum Volume in Practice: What Users Can Expect from NISQ Devices.” QV provides a standard benchmark to quantify the capability of NISQ devices. Interestingly, the QV values achieved in the tests (Pelofske et al., 2022) typically lag behind officially reported results and also depend significantly on the classical compilation effort. This is important to have in mind when popular articles announce QC breakthroughs in terms of higher QV values.

Relevance of metrics for usefulness

The definition of QV: $d = N$ stops short of benchmarking what is needed for useful applications. Useful algorithms often require the quantum circuit depth d to be much larger than the width N (number of qubits): $d \gg N$. This is typically the case when describing the ground-state energy of a molecule with reasonable accuracy. For example, a small molecule like HCN can be described (STO-6G basis) using Qiskit with $N = 15$ and $d \approx 33000 = 2200 N$ ($N = 14$ and $d \approx 3000 \approx 200 N$ within an optimized scheme of Tranter et al., 2022). Similarly, HCN (6–31 G basis) can be described using Qiskit with $N = 69$ and $d = 6 \times 10^6 \sim 87000 N$ (Lolur et al., 2021). These huge circuit depths can most likely be reduced with improved compilation methods (like in Tranter et al. (2022)), but nevertheless indicate the nature of the problem to perform useful calculations.

For comparison, instead of using random circuits and XEB or QV/HOG as targets, one can generate specific quantum states showing genuine multipartite entanglement (GME) with sufficient fidelity. Mooney et al. (2021) investigated multiple quantum coherences of Greenberger-Horne-Zeilinger (GHZ) states on 11–27 qubits prepared on the IBM Quantum Montreal (ibmq_montreal) device (27 qubits), applying quantum readout error mitigation and parity verification error detection to the states. In this way, a fidelity of $0.546 \pm 0.017 > 0.5$ was recorded for a 27-qubit GHZ state, demonstrating rare instances of GME across the full device.

Although this experiment may feel more interesting and useful than testing with random circuits, it nevertheless demonstrates that there is a very low probability for creating a 27-qubit GHZ state. For it to be useful, the GHZ state must be created with 100% probability to serve as starting point for useful information processing.

Applications

Quantum approximate optimization algorithm—QAOA

The quantum approximate optimization algorithm (QAOA) was proposed as a heuristic variational method for solving NP-hard combinatorial optimization problems on near-term quantum computers (Farhi et al., 2014; Farhi and Harrow, 2016), and constitutes one of the most widespread and active current methods for using NISQ computers (Farhi et al., 2022; Zhou et al., 2020; Morales et al., 2020; Zhang et al., 2022a; Harrigan et al., 2021; Herrman et al., 2021; Borle et al., 2021; Dupont et al., 2022; Chen et al., 2022b; Sreedhar et al., 2022; Willsch et al., 2020; Bengtsson et al., 2020; Fitzek et al., 2021; Lacroix et al., 2020; Weggemans et al., 2022; Verdon et al., 2019; Moussa et al., 2022; Patel et al., 2022; Bravyi et al., 2020, 2022; Egger et al., 2021; Guerreschi and Matsuura, 2019; Wurtz and Love, 2022; Chandarana et al., 2022; Hegade et al., 2022).

QAOA basics

The QPU prepares a variational quantum state $|\psi(\gamma, \beta)\rangle$ with N qubits starting from an initial uniform superposition of all possible computational basis states $|+\rangle^{\otimes N}$ generated by Hadamard gates from $|0\rangle^{\otimes N}$ (Fig. 4). The second step of QAOA is then to apply an alternating sequence $U = U(p), \dots, U(2)U(1)|+\rangle^{\otimes N}$ of two parametrized noncommuting quantum gates $U(i) = U(i, \beta_i)U(i, \gamma_i) = e^{-i\beta_i B}e^{-i\gamma_i C}$, followed by measurement generating an n -qubit bitstring. Many repetitions (shots) of the

Fig. 4 Quantum circuit for the quantum approximate optimization algorithm (QAOA). The QAOA for a problem specified by the Ising Hamiltonian $\hat{C}$. An alternating sequence of the Ising Hamiltonian $\hat{C}$ and the transverse mixing Hamiltonian $\hat{B}$ is applied to an equal superposition of N qubits, producing a trial state function $|\psi(\gamma, \beta)\rangle = \prod_{i=1}^p e^{-i\beta_i \hat{B}} e^{-i\gamma_i \hat{C}}$. Measurement of the qubit state produces a specific N -qubit bitstring, and many repetitions (shots) of the identical quantum circuit (loop not shown) creates a distribution used for estimating the cost function $\langle \psi(\gamma, \beta) | \hat{C} | \psi(\gamma, \beta) \rangle$. A classical optimization loop then minimizes the cost function by updating the variational parameters γ, β . The level p represents the depth of the circuit, determining the number of variational parameters and gates used in the trial function $|\psi(\gamma, \beta)\rangle$. A large circuit width N requires a (very) large depth p for accuracy. Adapted from Bengtsson A, et al. (2020) Quantum approximate optimization of the exact cover problem on a superconducting quantum processor. *Physical Review Applied* 14: 034010.

same circuit generate a distribution of bitstrings used to evaluate the cost function $\langle \psi(\gamma, \beta) | \hat{C} | \psi(\gamma, \beta) \rangle$. The variational parameters are then updated in a closed loop using a classical optimizer to minimize the cost function.

QAOA applied to air transportation—Tail assignment

Industrial optimization has a long history (Ong and Teo, 2021), one of the most famous applications being Toyota's Just-In-Time production system first implemented in 1973 (Monden, 2012). There is an extensive recent literature on optimization for industrial engineering and logistics (see e.g., de Sousa Junior et al., 2019; Csálódi et al., 2021; Ong and Teo, 2021; Monden, 2012), since around 2015 often referred to as Industry 4.0 (Csálódi et al., 2021; Rai et al., 2021).

In the following we will discuss one specific example addressing airline scheduling (Wedelin, 1995): the performance of the QAOA algorithm for optimizing small but realistic instances of logistic scheduling relevant to airlines. The problem addressed is called tail assignment (TAS) (Grönkvist, 2005; Vikstål et al., 2020; Svensson et al., 2021), assigning individual aircraft (identified by the number on its tail fin) to particular routes, deciding which individual aircraft (tail) should operate each flight.

A full approach to TAS is discussed in detail by Svensson et al. (2021), separating TAS into a generation problem and a selection problem. In this way, the complex rules only affect the generation problem, whereas the selection problem is often a pure Set Cover or Set Partitioning problem.

The TAS generation problem is responsible for generating the complex aircraft routes. A flight is a connection between two airports. A set of flights operated in sequence by the same aircraft (tail) is called a route (Vikstål et al., 2020). To formulate the TAS problem, let F denote the set of flights f , T the set of tails t , and R the set of all legal routes r . In order for a route to be considered legal to operate, it needs to satisfy a number of constraints.

In a full problem description one would include various costs, like the cost of flying a route and the cost of leaving a flight unassigned. In the decision version of TAS, the goal is to find any solution satisfying all the constraints, disregarding the costs. Essential aspects of the full TAS selection problem can then be reduced to an Exact Cover decision problem with the constraint

$$\sum_{r \in R} a_{fr} x_r = 1; \quad x_r \in \{0, 1\} \quad (2)$$

The constraint matrix $\{a_{fr}\}$ defines the relationship between F and R and tells whether a flight f is included in route r : $a_{fr} = 1$ if flight f is covered by route r and 0 otherwise. Given the generated constraint matrix $\{a_{fr}\}$, the solutions for the decision variable x_r will follow from the solution of the Exact Cover decision problem: $x_r = 1$ if route r should be used in the solution, and is 0 otherwise.

The constraint can be turned into a cost function

$$C = \sum_{f \in F} \left(\sum_{r \in R} a_{fr} x_r - 1 \right)^2 \quad (3)$$

that can be converted to the classical QUBO model—quadratic unrestricted binary optimization, which then maps over onto the quantum Ising model (Glover et al., 2022a, b; Ajagekar et al., 2022). In the final cost function, the Ising Hamiltonian, the constants (external field and spin interactions) are then determined by the constraint matrix $\{a_{fr}\}$ (Eq. 2).

Vikstål et al. (2020) reduced real-world instances obtained from real flight scheduling to instances with 8, 15, and 25 decision variables, which could be solved using QAOA on a quantum computer laptop simulator with 8, 15, and 25 qubits (routes), respectively. For these small instances, the problem was reduced to an exact cover problem with one solution in each instance. Elementary instances have been studied experimentally by Bengtsson et al. (2020) and Lacroix et al. (2020).

The same TAS problem was studied by Willsch et al. (2022) mapped onto a 40-qubit problem and 472 flights. For each of the 40 routes, the constraint matrix defines all flights that are covered by this route. As explained, the exact cover problem is to find a selection of routes (i.e., a subset of rows of the constraint matrix) such that all 472 flights are covered exactly once. The exact cover problem was programmed on D-Wave Advantage and 2000Q. The problem instance has the unique ground state $|0000000001010010011001000001000000000110\rangle$, where each qubit represents a flight route. The ground state contains nine 1's meaning that for this particular instance, the solution consists of nine routes. Each route is assigned to an aircraft. All other states represent invalid solutions, in the sense that not all 472 flights are covered exactly once. However, the fact that the D-Wave quantum annealers (simulators) were able to solve this problem does not imply quantum advantage (Kowalsky et al., 2022).

Variational quantum eigensolver—VQE

VQE basics

The VQE implements the Rayleigh-Ritz variational principle (Fig. 5) (Wendin, 2017; Lee et al., 2019):

$$E(\theta) = \langle \psi(\theta) | \hat{H} | \psi(\theta) \rangle \geq E_0 \quad (4)$$

The VQE is a classical-quantum hybrid algorithm where the trial function $|\psi(\theta)\rangle$ is created in the qubit register by gate operations. Calculating the expectation value on a QPU, the energy is estimated via repeated generation and readout of the quantum state, generating a distribution used to evaluate the Pauli operator products of $\hat{H}$. In quantum simulation on an HPC, the state vector is available classically, and the expectation value of $\hat{H}$ can be evaluated directly. The VQE scales badly for large molecules due to repeated measurements or tomography to form the expectation value of the Hamiltonian, $\langle \hat{H} \rangle$. Nevertheless, the VQE is the common approach for small molecules with present NISQ QPUs (Cao et al., 2019; McArdle et al., 2020; McClean et al., 2021; Fedorov et al., 2022). The PEA scales better, but involves much deeper circuits, puts much higher demands on the coherence time of the q-register, and needs advanced QEC.

VQE applied to chemistry

For an overview of applications to chemistry, see reviews (McArdle et al., 2020; McClean et al., 2021; Fedorov et al., 2022) and specific applications (Lee et al., 2019; Kim et al., 2022; Sokolov et al., 2020; Elfving et al., 2021; Sapova and Fedorov, 2022; Lolur et al., 2021; Tranter et al., 2022; Lolur et al., 2023; Sugisaki et al., 2019, 2022; Chen et al., 2021a; Zhang et al., 2022c; de Gracia-Treviño et al., 2023; Grimsley et al., 2019; Tang et al., 2021; Tkachenko et al., 2021; Lan and Liang, 2022).

Fig. 5 The Variational Quantum Eigensolver (VQE) implements the Rayleigh-Ritz variational principle: $E(\theta) = \langle \psi(\theta) | \hat{H} | \psi(\theta) \rangle \geq E_0$. The trial function $|\psi(\theta)\rangle$ is created as a quantum circuit by the HPC and sent to the backend QPU (or simulator). The gates are then executed in the QPU by pulses generated by the classical electronics and software control system in the stack. The quantum register is finally measured, producing a bitstring used to evaluate the Hamiltonian cost function $\hat{H}$. This is repeated many times to evaluate the energy $\langle \psi(\theta) | \hat{H} | \psi(\theta) \rangle$ with sufficient accuracy. The optimization loop then updates the parameters $\{\theta_i\}$ to minimize the energy.

In VQE calculations for quantum chemistry (Wendin, 2017; Lee et al., 2019), one typically starts from an ansatz of the quantum state $|\psi(\theta)\rangle = U(\theta)|\psi_{ref}\rangle$ with variational parameters θ , where $U(\theta)$ is a unitary operator describing the quantum circuit, and $|\psi_{ref}\rangle$ is the initial state. $U(\theta)$ could be a heuristic “hardware efficient” quantum circuit (Kandala et al., 2017) or a more elaborate unitary coupled cluster (UCC) expansion, with a Hartree-Fock (Wendin, 2017; Lee et al., 2019; Sokolov et al., 2020) or multiconfiguration (Sugisaki et al., 2019, 2022) initial reference state.

The UCC ansatz of the quantum state $|\psi(\theta)\rangle$:

$$|\psi(\theta)\rangle = \hat{U}(\theta)|\psi_{ref}\rangle = e^{T(\theta) - T(\theta)^\dagger} |\psi_{ref}\rangle \quad (5)$$

can be expanded:

$$T(\theta) = T_1 + T_2 + T_3 + \dots + T_N \quad (6)$$

producing 1, 2, 3, ..., N electron-hole excitations from the N -electron reference state. The first two terms

$$T_1 = \sum_{pq} t(\theta)_{pq} c_p^\dagger c_q; \quad T_2 = \sum_{pqrs} t(\theta)_{pqrs} c_p^\dagger c_q^\dagger c_r c_s \quad (7)$$

with fermionic creation ($c_i^\dagger$) and annihilation (c_i) operators generate single (S) and double (D) excitations and produce the parametrized UCCSD trial-state approximation. In particular $t(\theta)_{pq} = \theta_i$ and $t(\theta)_{pqrs} = \theta_j$ for all combinations of the indices $pqrs$.

The trial-state fermionic operator $U(\theta)$ must now be mapped onto qubit spin operators. Common transformations (codings) are Jordan-Wigner (JW), Bravyi–Kitaev (BK) and Parity, all designed to impose the anticommutation rules. In the case of the UCC ansatz, the exponential is expanded into exponentials of large numbers of products of Pauli spin operators acting on qubits. The initial trial state is then constructed through entangled quantum circuits: combinations of parametrized 1q-rotation gates and entangling 2q gates. The size of the quantum circuit can finally be reduced by qubit reduction schemes. All this results in a state vector for the trial state.

The fermionic operators $c_i^\dagger$ and c_i in the molecular Hamiltonian

$$\hat{H} = \sum_{pq} h_{pq} c_p^\dagger c_q + \frac{1}{2} \sum_{pqrs} h_{pqrs} c_p^\dagger c_q^\dagger c_r c_s \quad (8)$$

must also be expanded in products of Pauli spin operators using codings like JW, BK, or Parity, resulting in the generic interaction form:

$$\hat{H} = \sum_{ix} h_{ix} \sigma_{ix} + \sum_{ix, j\beta} h_{ix, j\beta} \sigma_{ix} \sigma_{j\beta} + \sum_{ix, j\beta, k\gamma} h_{ix, j\beta, k\gamma} \sigma_{ix} \sigma_{j\beta} \sigma_{k\gamma} + \dots \quad (9)$$

where σ_{ix} corresponds to the Pauli matrix σ_α for $\alpha \in \{0, x, y, z\}$, acting on the i -th qubit. The expectation value $\langle \hat{H} \rangle$ can then be calculated in two ways: (1) State vector approach: direct calculation of by matrix operations; (2) Measurement approach: generating an ensemble of identical trial states and evaluating the Pauli operators of the Hamiltonian terms $\hat{H}_i$.

The original UCC exponential (Eq. 5) is then expanded into exponentials of large numbers of products of Pauli spin operators acting on qubits: $e^{-i\theta\sigma_{1z}\sigma_{2z}}$, $e^{-i\theta\sigma_{1z}\sigma_{2z}\sigma_{3z}}$, etc. The parametrized initial entangled quantum circuit $U(\theta)$ for the UCCSD trial state is then finally constructed through combinations of parametrized one-qubit rotation gates and entangling two-qubit CNOT gates, resulting in a state vector $|\psi(\theta)\rangle = U(\theta)|\psi_{HF}\rangle$ for the trial state.

Lolur et al. (2021) have benchmarked the VQE as implemented in the Qiskit software package on laptops and HPCs, applying it to computing the ground state energy of water, H_2O , hydrogen cyanide, HCN, and a number of related molecules.^a The energies have been determined using the noise-free Qiskit statevector backend to directly calculate $\langle \psi(\theta) | \hat{H} | \psi(\theta) \rangle$ through matrix multiplication rather than repeated measurement. Clearly, substantial classical computational resources are needed to compute these systems on classical HPC quantum simulators. It is evident that for problems with QChem-inspired ansätze, even small numbers of qubits lead to large numbers of gates. And this is then amplified by the variational procedure with many parameters and iterations. The large number of gates will severely limit the types of molecules that can be used for benchmarking real quantum HW. And it will also limit what can be simulated on HPC quantum simulators. QChem problems will provide serious challenges and benchmarks for testing HPC and quantum HW NISQ implementations.

To utilize VQE and achieve near chemical accuracy will be extremely challenging for NISQ processors. It is problematic or impossible to achieve chemical accuracy with conventional HPC VQE simulators already for small molecules such as HCN. But, there is no way around it: one must benchmark and challenge existing quantum HW and SW with available resources. The water molecule is a kind of “gold standard” even for forefront HPC applications, and H_2O is an excellent candidate for testing the VQE on

^aWendin G., “The Main Results of Lolur et al. (2021) are Produced with an iMac i9, 8-Cores Workstation with 128 GB RAM (max 32 Qubits). The Practical Limit for the iMac to Achieve an Accurate Ground-State Energy Minimum is so far Connected with H_2O (6-31G): 20 Qubits and 73 000 Gates, Taking 66.5 Hours to Converge to 10–6 Ha Precision of the Ground-State Energy for the Equilibrium Geometry. In the Case of $\text{N}=\text{C}=\text{C}=\text{N}$ (STO-6G): 29 Qubits, 2815 Variational Parameters, 515611 Gates) it Took 132 CPU-Hours (5.5 days) to Produce the First Energy Value. This Must then be Multiplied by 2815 to Evaluate one Gradient Vector for the First Energy Estimate by the Optimizer. And then this will need to be Iterated at Least 10 Times to Converge to an Accurate Ground State Energy Value. The Time-to-Solution (TTS) is then about $3.7 \cdot 10^6$ CPU-Hours. For Comparison, SUMMIT at ORNL, USA, with in total 202752 Cores, Would Finish the $\text{N}=\text{C}=\text{C}=\text{N}$ Instance in 147 Hours = 6 days. In the QChem Case, the Challenge Lies in the Number of Variational Parameters and the number of Gates Needed, not in the number of Qubits. Smart Compilation can Greatly Reduce the number of Gates Tranter et al. (2022), but does not really change the poor scaling.

quantum HW. Nevertheless, at the present stage of the NISQ era, one has to start with “easy” applications and simple approximations just to benchmark the quantum HW.

The concept of “hardware-efficient” trial functions (Kandala et al., 2017) is an attempt to short-circuit standard UCCSD approaches and still introduce essential electron correlation. The recently developed adaptive VQE (Grimsley et al., 2019; Tang et al., 2021) and related further developments (Tkachenko et al., 2021; Lan and Liang, 2022) provide a more systematic approach to including electron correlation processes in order of monotonically decreasing weight. Nevertheless, the electron-correlation problem is computationally hard (NP-hard), so there is no easy way around it. State-of-the-art HPC computation of accurate molecular energies based on the Schrödinger equation defines the resources needed, and they are indeed huge (Calvin et al., 2021; Jones et al., 2022).

HPC quantum simulators cannot be more efficient than systematic HPC brute-force full CI calculations. Quantum advantage will be possible by definition as soon as a quantum register exceeds the available RAM memory of an HPC. But to profit from that potential quantum advantage, the QPU must be able to run the q-algorithm to solution, and that will involve a very large number of gate operations even for the VQE. So, this is the ultimate challenge of the NISQ era.

Simulating physical systems on engineered quantum platforms

Feynman’s original idea was to simulate quantum systems with engineered quantum systems. Using analog quantum circuits one tunes the interactions in a controllable quantum substrate to describe the Hamiltonian of the system to be simulated, and then anneals the systems toward their ground states by lowering the temperature.

A comprehensive review (Daley et al., 2022) describes how quantum simulation can be performed already today through special-purpose analog HW quantum simulators, arguing that a first practical quantum advantage already exists in the case of specialized applications of analog devices. A particular example is simulation of 2D antiferromagnets with hundreds of Rydberg atoms trapped in an array by optical tweezers (Scholl et al., 2021), and the development of digital-analog QS for superconducting circuits (Lamata et al., 2018; Yu et al., 2022).

The recent development of large-scale superconducting arrays makes it possible to design qubit circuits that simulate a specific physical device, and perform experiments on it (Arute et al., 2020b; Neill et al., 2021; Gong et al., 2021; Mi et al., 2022b; Zhang et al., 2022b; Karamlou et al., 2022; Landsman et al., 2019; Touil and Deffner, 2020; Mi et al., 2021; Braumüller et al., 2022; Frey and Rachel, 2022; Mi et al., 2022a). In this way, Arute et al. (2020b) simulated separation of the dynamics of charge and spin in the Fermi-Hubbard model, Neill et al. (2021) simulated the electronic properties of a quantum ring created in the Sycamore substrate, and Mi et al. (2022b) investigated discrete time crystals in an open-ended, linear chain of 20 superconducting transmon qubits that were isolated from the two-dimensional Sycamore grid. Kim et al. (2023) studied the evolution of quench dynamics of a 2D transverse-field Ising model with up to 26 spins on a 27q IBM Falcon processor, and similar experiments with the 127q Eagle processor are in the pipeline. In this case the results may be classically intractable.

We will now discuss a few recent experiments addressing transport, information scrambling, and scarring in quantum circuits.

Quantum transport and localization

Tight-binding lattice Hamiltonians are canonical models for particle transport and localization phenomena in condensed-matter systems. To study the propagation of entanglement and observe Anderson and Wannier–Stark localization, Karamlou et al. (2022) experimentally investigated quantum transport in one- and two-dimensional tight-binding lattices, emulated by a fully controllable 3×3 array of superconducting qubits in the presence of site-tunable disorder strengths and gradients.

The dynamics are hard to observe in natural solid-state materials, but they can be directly emulated and experimentally studied using engineered quantum systems. The close agreement between the experimental results, simulations, and theoretical predictions (Karamlou et al., 2022) results from high-fidelity, simultaneous qubit control and readout, accurate calibration, and taking into account the relevant decoherence mechanisms in the system.

Karamlou et al. (2022) emphasize that although the experiments are performed on a small lattice that can still be simulated on a classical computer, they demonstrate a platform for exploring larger, interacting systems where numerical simulations become intractable.

Quantum information scrambling

Quantum scrambling is the dispersal of local information into many-body quantum entanglements and correlations distributed throughout an entire system, leading to the loss of local recoverability of quantum information (Landsman et al., 2019; Touil and Deffner, 2020; Mi et al., 2021; Braumüller et al., 2022).

Following Mi et al. (2021), the approach is based on measuring the out-of-time-order correlator (OTOC) $C = \langle |\hat{O}^*(t)\hat{M}^*\hat{O}(t)\hat{M}| \rangle$ between a unitary local perturbation operator $\hat{O}(t)$ and unitary operator $\hat{M}$ which is a Pauli operator on a different qubit. Scrambling means a local perturbation is rapidly amplified over time. During the time evolution, $\hat{O}(t)$ becomes increasingly nonlocal, which leads to decay of correlation function due to the spreading of the excitation all over the system.

The perturbation operator can be modeled as $\hat{O}(t) = \sum_i w_i \hat{B}_i$, where $\hat{B}_i = b_1(i) \otimes b_2(i) \otimes b_3(i) \dots$ is a string of single-qubit basis operators acting on different qubits, and w_i are the weights of the operator strings. Scrambling involves two different mechanisms: (i) Operator spreading, and (ii) generation of operator entanglement. Operator spreading (i) means that the strings of single-qubit

basis operators $\hat{B}_i$ get expanded, spreading over more qubits, while (ii) generation of operator entanglement is reflected in the growth in time of the minimum number of terms needed to expand $\hat{O}(t) = \sum_i w_i \hat{B}_i$ with a broad distribution of coefficients w_i .

By measuring the OTOC, Mi et al. (2021) experimentally investigated the dynamics of quantum scrambling on a 53-qubit Sycamore quantum processor. Engineering quantum circuits that distinguished between operator spreading and operator entanglement, they showed that operator spreading is captured by an efficient classical model, while operator entanglement in idealized circuits requires exponentially scaled computational resources to simulate. However, the quantum-supremacy discussion of the influence of noise, making possible classical simulation of large noisy QPUs, suggests that the noise level needs to be reduced substantially before exponentially scaled computational resources are needed.

Recently Braumüller et al. (2022) also probed quantum information propagation with out-of-time-ordered correlators (OTOCs). They implemented a 3×3 two-dimensional hard-core Bose–Hubbard lattice with a superconducting circuit, studied its time reversibility, and measured out-of-time-ordered correlators. The method relies on the application of forward and backward time evolution steps implemented by interleaving blocks of unitary time evolution and single-qubit gates. Extracting OTOCs made it possible to study quantum information propagation in lattices with various numbers of particles, enabling observation of a signature of many-body localization in the 2D hard-core Bose–Hubbard model.

Braumüller et al. (2022) propose that applying the technique to larger lattices may improve our understanding of quantum thermodynamics and black-hole dynamics, as well as of using many-body systems for quantum memories. In addition, experimentally accessing OTOCs in large quantum circuits may provide a powerful benchmarking tool to study future quantum processors. But again, here noise will likely become an issue.

Many-body Hilbert space scarring

Moudgalya et al. (2022) and Chandran et al. (2023) recently presented reviews of work on quantum many-body scars and Hilbert space fragmentation, describing dynamical process that is weakly nonergodic, not completely filling the entire phase space.

Zhang et al. (2022b) and Chen et al. (2022a) studied many-body Hilbert space scarring (QMBS) on superconducting processors. QMBS is a weak form of ergodicity breaking in strongly interacting quantum systems, meaning that the system does not visit all parts of phase space. This presents opportunities for mitigating thermalization-induced decoherence due to scrambling in quantum information processing applications.

Utilizing a programmable superconducting processor with 30 qubits and tunable couplings, Zhang et al. (2022b) created Hilbert space scarring in a nonconstrained model in different geometries, including a linear chain and quasi-one-dimensional comb geometry, by approximately decoupling from the qubit substrate. By reconstructing the full quantum state through quantum state tomography on four-qubit subsystems, they present strong evidence for QMBS states by measuring qubit population dynamics, quantum fidelity, and entanglement entropy after a quench from initial unentangled states. The QMBS is found to be robust to various imperfections such as random cross-couplings between qubits, and it persists beyond 1D systems. The experimental findings also broaden the realm of scarring mechanisms and identify correlations in QMBS states for quantum technology applications. Comparing with other qubit platforms, Zhang et al. (2022b) state that the superconducting platform can process the same quantum information in a shorter time, implying advantages of QMBS in a superconducting platform for more practical quantum-sensing and metrology applications.

Also, Chen et al. (2022a) recently used pulse-level control and a variety of quantum error-mitigation (QEM) techniques to simulate the dynamics of a spin chain with QMBS on IBM QPUs for chains of up to 19 qubits. They conclude that the results demonstrate the power of error-mitigation techniques and pulse-level control to probe many-body coherence and correlation effects on present-day quantum hardware.

Key issues

Noise and loss of information—A common experience

A common classical experience might illuminate what QC is facing in the present NISQ era. Onboard an airplane, listening to music using the cheap versions of headphones offered by airlines in economy class can be a less-than-satisfactory experience. To start with, the headphone sound emitters have narrow bandwidth and large distortion, certainly not improving the limited quality of the source itself. Then the high-frequency background noise in the cabin from the air conditioning and engines may swamp the music signal. And finally, the sensitivity and frequency response of passenger's ears, and the processing in the brain (CPS, 2023; CAPD, 2023; Souffi, 2023), may be less than perfect, making it difficult to discriminate against the noise. For the traveler, high-quality headphones with noise suppression therefore make a big difference. Then the external noise from the environment is processed in real time: recorded, inverted, and subtracted.

This is a useful analogy in the case of a single qubit in a noisy environment. However, in order to describe the influence of noise on a multiqubit processor, one might better illustrate the situation in terms of the “Cocktail Party Syndrome” (CPS, 2023), referring to the difficulty to entertain a meaningful conversation within a group of people in a very noisy environment. Here, also simultaneous “two-body interactions” between members of the group add “correlated” noise to the “random” noise from the background.

In our classical example, one can informally define error suppression, error mitigation, and error correction: Error suppression means creating high-quality hardware: the signal input is perfect; the classical bits are perfect; the sound generators in the

headphones are perfect. Error mitigation means eliminating background cocktail party (channel) noise, for example, via noise inverting devices, as well as eliminating noise generated within the group (e.g., noise within the brain from alcohol consumption and tinnitus). Error mitigation would also include recording of the session and providing a clean edited transcript afterwards (postprocessing). Error correction means coding the information such that any errors can be traced and corrected, in real time or at the end.

When it comes to real quantum computers, similar concepts and actions apply: one talks about quantum error suppression (QES), quantum error mitigation (QEM), and quantum error correction (QEC).

Fighting imperfections and noise in quantum processors

Key issues concern the impact of imperfections and noise on computational capacity. NISQ devices are noisy, which creates decoherence and computational errors due to qubit relaxation and dephasing. One talks about three main types of noise: incoherent, coherent, and correlated. JJ qubits are embedded in a sea of fluctuating defects creating stochastic charge fluctuations—incoherent noise—capable of driving unwanted qubit transitions causing relaxation. Moreover, qubit control via microwave waveguides and magnetic flux lines is subject to stochastic fluctuations influencing the precision of quantum operations. These fluctuating fields may lead to incoherent dephasing of individual qubits, as well as to systematic miscalibrations, drift, and crosstalk—coherent noise—that in principle can be reversed (Krantz et al., 2019; Hashim et al., 2021; Ahsan et al., 2022). Finally, recent work shows that impact of cosmic rays can generate quasiparticles that create correlated charge noise and qubit relaxations on a length scale of hundreds of micrometers (Vepsäläinen et al., 2020; Wilen et al., 2021).

Quantum error suppression

QES refers to various efforts to maximize the QV by improving the fabrication and operation of the quantum hardware (HW). (This excludes active feedback, treated as QEC).

On the fabrication side, the main issues concern minimizing decoherence (Krantz et al., 2019; Burnett et al., 2019; Vepsäläinen et al., 2020; Wilen et al., 2021; Spring et al., 2022; Müller et al., 2019; Bilmes et al., 2020; Carroll et al., 2022) and cross talk (Zhao et al., 2022; Spring et al., 2022). For a given QPU circuit, the issue is to maximize gate fidelities and speed via optimal control (e.g., pulse shaping) based on advanced characterization of the device (Wittler et al., 2021).

Quantum error mitigation

QEM aims to produce accurate expectation values of observables. It refers to various software methods to alleviate the effects of noise on computational results during execution of an algorithm on a QPU (Temme et al., 2017; Li and Benjamin, 2017; Kandala et al., 2017; Endo et al., 2018; Song et al., 2019; van den Berg et al., 2022; Takagi et al., 2022; Lolur et al., 2023).

QEM effectively involves creating a noisy distribution of results, and then extracting the desired quantum information via postprocessing. Currently, the main principles are zero-noise extrapolation (ZNE) (Temme et al., 2017; Li and Benjamin, 2017; Kandala et al., 2017; Endo et al., 2018) and probabilistic error cancellation (PEC) (Temme et al., 2017; Li and Benjamin, 2017; Endo et al., 2018; Song et al., 2019; van den Berg et al., 2022; Takagi et al., 2022). The first scheme (ZNE) does not make any assumption about the noise model other than it being weak and constant in time (Temme et al., 2017). The second scheme (PEC) can tolerate stronger noise; however, it requires detailed knowledge of the noise model (Temme et al., 2017).

ZNE works by physically increasing the impact of noise, determining a curve describing how the expectation value of some observable varies with noise. Variation of the noise strength can be done or simulated by varying the 1q- and 2q-gate times. Given enough points to determine the variation, the curve is then extrapolated back to zero noise, providing a best estimate of the expectation value. This has been implemented successfully in a number of experimental and theoretical investigations (Kandala et al., 2019; Giurgica-Tiron et al., 2020; Schultz et al., 2022; Pascuzzi et al., 2022; Kim et al., 2023).

The ZNE requires sufficient control of the time evolution to implement the rescaled dynamics and hinges on the assumption of a large time-scale separation between the dominant noise and the controlled dynamics (Temme et al., 2017).

PEC works by measuring the noise spectrum and applying an inverted quasiprobability distribution to the result of the computation via postprocessing (Temme et al., 2017; Li and Benjamin, 2017; Endo et al., 2018; Song et al., 2019; van den Berg et al., 2022; Takagi et al., 2022). PEC requires a full characterization of the noisy computational operations. To obtain this to sufficient precision is challenging in practice (Temme et al., 2017). Nevertheless, Song et al. (2019) experimentally demonstrated that PEC based on a combination of gate set tomography (GST) and quasiprobability decomposition can substantially reduce the error in quantum computation on a noisy quantum device. Moreover, van den Berg et al. (2022) have presented a practical protocol for learning and inverting a sparse noise model that is able to capture correlated noise and scales to large quantum devices, demonstrating PEC on a superconducting quantum processor with crosstalk errors.

In contrast, Leyton-Ortega et al. (2023) present a method to improve the convergence of variational algorithms by replacing the hardware implementation of certain Hermitian gates with their inverses, resulting in noise cancellation and a more resilient quantum circuit. This is demonstrated on superconducting quantum processors running the VQE algorithm to find the H_2 ground-state energy.

Another QEM method has been developed by Lolur et al. (2023) for quantum chemical computations on NISQ devices—Reference-State Error Mitigation (REM). The method relies on determining the exact error in energy due to hardware and

environmental noise for a reference wavefunction that can be feasibly evaluated on a classical computer. REM is shown to drastically improve the computational accuracy at which total energies of molecules can be computed using current quantum hardware.

Quantum error correction

QEC refers to methods to code quantum information into logical qubits that can be measured, errors detected and identified, and logical qubits restored (Fowler et al., 2012; Kelly et al., 2015; Terhal, 2015; Wendin, 2017; Roffe, 2015; Bravyi et al., 2022; Ryan-Anderson et al., 2021, 2022; Postler et al., 2022; Andersen et al., 2020; Marques et al., 2022; Chen et al., 2021b; Krinner et al., 2022; Acharya et al., 2023; Piveteau et al., 2021; Ouyang, 2021; Suzuki et al., 2022). The initial application of the surface code to superconducting devices (Kelly et al., 2015) was followed up by several groups (Andersen et al., 2020; Marques et al., 2022; Chen et al., 2021b), and has recently resulted in demonstrations of repeated cycles of QEC. Krinner et al. (2022) implemented a 17-qubit distance-3 surface code, while Acharya et al. (2023) implemented a 49-qubit distance-5 code.

Acharya et al. (2023) draw particular attention to the question whether scaling up the error-correcting code size will reduce logical error rates in a real device. They answer it by reporting on a 72-qubit superconducting device supporting a 49-qubit distance-5 ($d = 5$) surface code that narrowly outperforms its average subset 17-qubit distance-3 ($d = 3$) surface code, demonstrating a critical step toward scalable QEC.

Even though John Martinis' group at USCB in 2014 announced that superconducting quantum circuits were at the surface code threshold for fault tolerance (Barends et al., 2014), this did not mean that the route to QEC was a straight one—it is all about scaling. When the physical error rate is high, the logical error probability increases with increasing system size while sufficiently low physical error rates will eventually lead to the desired exponential suppression of logical errors.

Acharya et al. (2023) show that their experiment lies in a crossover regime where increasing system size initially suppresses the logical error rate before, due to finite-size effects, later increasing it. They estimate that component performance must improve significantly to achieve practical scaling. In any case, the work demonstrates the first step in the process of suppressing logical errors by scaling up a quantum error-correcting code.

Scaling up for practical quantum advantage

The concept of quantum advantage (QA) has emerged as a reaction to the more dramatic notion of quantum superiority (QS) (Preskill, 2012). In principle, QS is what we need—exponential advantage of over classical computers. However, this is only possible with functional QEC. QA emphasizes enhanced performance relative to specific classical algorithms for real-world use cases, typically addressing variational problems like QAOA and VQE.

Currently there seems to be two opposite uses of practical QA: (i) effectively describing QS in huge QEC machines and (ii) mainly providing some useful speedup relative to classical algorithms. In the present NISQ era, there are essentially two ways to look at the scaling up of QPUs, what we will refer to as *QPU-centric* and *HPC-centric*.

QPU-centric approach

Here QPUs are scaled up in tune with HW progress to push the limits in experiments testing quantum supremacy (Arute et al., 2019; Wu et al., 2021; Zhu et al., 2022), QEC (Andersen et al., 2020; Chen et al., 2021b; Marques et al., 2022; Krinner et al., 2022; Acharya et al., 2023), and physics (Barends et al., 2015, 2016; Kandala et al., 2017, 2019; Gong et al., 2019; Arute et al., 2020b, a; Neill et al., 2021; Gong et al., 2021, 2022; Zhang et al., 2022b; Mi et al., 2022b; Stanisic et al., 2022). The main role of the classical computer is to serve a single “free-standing” QPU with pre- and post-processing resources for running quantum circuits. The maximum number of qubits in the QPU so far is 72 (Acharya et al., 2023). Further scaling up the number of qubits will make it possible to systematically build larger logical qubits and larger code distances. In a blog post in May 2021, Erik Lucero at Google (Lucero, 2021) began with a bold statement: “Within the decade, Google aims to build a useful, error-corrected quantum computer.” The key issue in 2029 will most likely be “useful to whom?” Researchers or industry?

HPC-centric approach

Here the HPC supercomputer seamlessly integrates collections of parallel CPUs, GPUs, and QPUs. The quantum big picture is to boost classical performance by including QPU subroutines approximately solving specific NP-hard problems that form classical bottlenecks. In this sense, the IBM roadmap and philosophy look *HPC-centric*, even though it is described by IBM rather as quantum-centric supercomputing (Gambetta, 2022a; Bravyi et al., 2022). The maximum number of qubits is currently 433, in the Osprey QPU (IBM, 2022). Osprey will be operated as a system of small parallel QPUs to achieve a computational advantage in the near term by combining multiple QPUs through circuit knitting techniques (Bravyi et al., 2022; Piveteau and Sutter, 2022), improving the quality of solutions through error suppression and mitigation, and focusing on heuristic versions of quantum algorithms with asymptotic speedups. Much of this is controlled by fast electronics and software that must effectively be incorporated as a dedicated HPC in the QPU stack. In this sense, the IBM approach is indeed QPU-centric, and the HPC mainframe becomes more of a server. The work distribution between the HPC and the QC/QPU is basically floating, and the terminology rather reflects HPC/QC attitudes: who serves who?

The IBM Q Experience has created an ecosystem based on Qiskit, providing a versatile programming and testbed environment (García-Pérez et al., 2020; Bravyi et al., 2022), beginning to emerge as an industry standard. However, superpolynomial speedup does not belong to the NISQ era, and practical quantum advantage is elusive. Realistically, industrial users will not profit from

quantum accelerators in the near term, so how can this large quantum effort be justified? The answer seems to be that IBM is going for useful quantum advantage via quantum parallel processing provided by QPU accelerators integrated in an efficient runtime HPC environment. Again the question is: useful to whom? Researchers or industry? And is useful quantum advantage possible without QEC?

The quantum volume (QV) effectively represents the size of a qubit register for which one can entangle all of its qubits in a single shot. Currently, for IBM the best published value is $QV = 2^9 = 512$, corresponding to a 9-qubit quantum circuit 9 levels deep. This means that there is no point running algorithms requiring more than that. Instead, one can configure the operating system to run a number of 9-qubit mini-QPUs in parallel to speed up the rate for creating measured distributions, thus reducing the time to solution for computing expectation values of physical variables, like energy.

Scale, quality, and speed are three key attributes to measure the performance of near-term quantum computers (Gambetta, 2022a; Bravyi et al., 2022). In the NISQ era, the QPU will spend very little time computing compared with the time spent by the CPU on pre- and post-processing before and after every call to the QPU. Calls that will be very frequent when solving variational problems. Circuit Layer Operations per Second (CLOPS) (Wack et al., 2021) is a measure correlated with how many QV circuits (mini-QPUs) a QPU can execute per unit of time, therefore shortening the time to solution.

At the IBM Summit 2022, Gambetta (2022b) pledged that in 2024, IBM will offer a system that will generate reliable outcomes running 100 qubits with gate depth of 100: "So creating this 100×100 device will really allow us to set up a path to understand how can we get quantum advantage in these systems and lay a future going forward." It must be noted, however, that this does not mean executing a 100q quantum circuit with depth 100 coherently "in a single shot," achieving $QV = 2^{100}$ —that would be a quantum-earth shaking demonstration of quantum supremacy.

Microsoft has developed a framework for quantum resource estimation (Beverland et al., 2022) to estimate resources required across the stack layers for large-scale quantum applications, finding (as expected) that hundreds of thousands to many millions of physical qubits are needed to achieve practical quantum advantage. Beverland et al. (2022) maintain that the best solution is a monolithic QPU with, say, 10 million controllable, fast, and small qubits. The stack control system must be able to run millions of parallel high-fidelity gates at high speed, as well as reading out millions of qubits in parallel.

Not surprisingly, no qubit technology currently implemented satisfies all of these requirements. However, Microsoft suggests that the recent proposals of electro-acoustic qubits (Chamberland et al., 2022) and the topological qubit approach based on Majorana Zero Modes (MZMs) (Karzig et al., 2017) might do it in future. Practical quantum advantage is on the horizon but needs to be accelerated through a variety of breakthrough techniques. The Microsoft view is that these research directions can be best studied in the context of resource estimation to unlock quantum at scale.

Useful NISQ digital quantum advantage—Mission impossible?

The short answer is: yes, unfortunately probably mission impossible in the NISQ era. There are two fundamental questions: (1) Does the physical problem itself provide a quantum advantage? and (2), does a quantum algorithm have any advantage over a corresponding classical algorithm?

Both questions were the original drivers of QC: the exponential advantage of Shor's algorithm for factorization into prime numbers. However, the need for QEC put that problem far in the future. Instead, Matthias Troyer and coworkers (Reiher et al., 2017) promoted quantum chemistry for catalysts as the most useful killer application motivating the quest for scaling up QC. The paper argues that "quantum computers will be able to tackle important problems in chemistry without requiring exorbitant resources," but at the same time concludes that "The required space and time resources for simulating FeMoco are comparable to that of Shor's factoring algorithm." Berry et al. (2019) improved on those results, obtaining circuits requiring less surface code resources, despite using a larger and more accurate active space. Nevertheless, also this needs extensive QEC and is far beyond NISQ computers. Liu et al. (2022) further elaborate on the potential benefits of QC in the molecular sciences, that is, in molecular physics, chemistry, biochemistry, and materials science, emphasizing the competition with classical methods that will ultimately decide on the usefulness of quantum computation for molecular science. Lee et al. (2022) have examined the case for the exponential quantum advantage (EQA) hypothesis for the central task of ground-state determination in quantum chemistry. Key for EQA is for the quantum state preparation to be exponentially easy compared to classical heuristics, which is far from clear and perhaps not even likely (Wang et al., 2021; Bittel and Kliesch, 2021). Identifying relevant quantum chemical systems with strong evidence of EQA remains an open question (Lee et al., 2022).

The second question: "does a quantum algorithm have any advantage over a corresponding classical algorithm?" is currently a hot topic. Understanding whether, for example, quantum machine learning (QML) algorithms present a genuine computational advantage over classical approaches is extremely challenging. It seems that quantum-inspired classical algorithms "dequantizing" quantum algorithms (Tang, 2021, 2022; Cotler et al., 2021; Gharibian and Gall, 2022) can compete in polynomial time as long as one is not demanding exponentially accurate results.

Tang and coworkers (Tang, 2022) developed a dequantization framework for analyzing QML algorithms to produce formal evidence against EQA. These are fully classical algorithms that, on classical data, perform only polynomially slower than their quantum counterparts. The existence of a dequantized algorithm means that its quantum counterpart cannot give exponential speedups on classical data, suggesting that the quantum exponential speedups are simply an artifact of state preparation assumptions. QML has the best chance of achieving large speedups whenever classical computation cannot get access to this data (which occurs when input states come from quantum circuits and other physical quantum systems). This does not yet rule out the

possibility of large polynomial speedups on classical data, which could still lead to significant performance improvements in practice with sufficiently good quantum computers (Tang, 2022).

Lloyd et al. (2016), however, proposed an algorithm for topological data analysis (TDA) that could not to be directly dequantized using the same techniques, raising the question whether a greater speedup was possible with TDA algorithms. This question has now been analyzed in depth by Berry et al. (2022), proposing a dequantization of the quantum TDA algorithm which shows that having exponentially large dimension and Betti number is necessary for superpolynomial advantage. The speedup is quartic, which will not be killed by QEC overhead (Babbush et al., 2021). Based on that, Berry et al. (2022) estimate that tens of billions of Toffoli gates will be sufficient to estimate a Betti number that should be classically intractable. This number of Toffoli gates is considered to be reasonable for early generations of fully fault-tolerant quantum computers (Berry et al., 2022), falling somewhere in between quantum chemistry applications and Shor's algorithm in terms of the resources required for quantum advantage.

Recently Akhmalwaya et al. (2022) presented an NISQ-TDA QML algorithm needing only a short circuit depth with provable asymptotic speedup for certain classes of problems. How this goes together with Berry et al. (2022) remains to be understood in greater depth, as nicely explained by Quanta Magazine (Parshall, 2022), pointing out that the number of high-dimensional holes needs to be unthinkably large for quantum advantage.

Reconnecting here to quantum chemistry, Gharibian and Gall (2022) have shown how to design classical algorithms that estimate, with constant precision, the singular values of a sparse matrix, implying that the ground state energy in quantum chemistry can be solved efficiently with constant precision on a classical computer. However, Gharibian and Gall (2022) also prove that with inverse-polynomial precision, the same problem becomes BQP-complete, suggesting that the superiority of quantum algorithms for chemistry stems from the improved precision achievable in the quantum setting.

Finally, Huang et al. (2022) investigate quantum advantage in learning from experiments that processes quantum data with a quantum computer. That could have substantial advantages over conventional experiments in which quantum states are measured and outcomes are processed with a classical computer. Huang et al. (2022) prove that quantum machines can learn from exponentially fewer experiments than the number required by conventional experiments. They do that by assuming having access to data obtained from quantum-enhanced experiments like quantum sensing systems and stored in quantum memory (QRAM), allowing the QPU to process quantum input data. Exponential advantage is shown for predicting properties of physical systems, performing quantum principal component analysis, and learning about physical dynamics. Huang et al. (2022): "Although for now we lack suitably advanced sensors and transducers, we have conducted proof-of-concept experiments in which quantum data were directly planted in our quantum processor."

In the absence of perfect physical qubits, or QEC, quantum memory is a great challenge. Quantum memory may be far away for QC as needed by, for example, Huang et al. (2022), but it is essential for the development of quantum repeaters for quantum communication networks. O'Sullivan et al. (2022) investigate random-access quantum memory using chirped-pulse phase encoding. The protocol is implemented using donor spins in silicon coupled to a superconducting cavity, offering the potential for microwave random access quantum memories with lifetimes exceeding seconds.

Future directions

Improved and alternative superconducting qubits

A recent comprehensive review by Calzona and Carrega (2023) describes and analyzes the basic concepts and ideas behind the implementation of novel superconducting circuits with intrinsic protection against decoherence at the hardware level. The review explains the basics and performance of state-of-the-art transmons and other single-mode superconducting quantum circuits, and goes on to describe multimode superconducting qubits, toward the realization of fully protected qubits engineered in systems with more than one degree of freedom and/or characterized by the presence of specific symmetries.

Regarding state-of-the-art tantalum-based transmons Place et al. (2021), Wang et al. (2022b) and Tennant et al. (2022) performed low-frequency charge-noise spectroscopy on Ta-based transmons and found distinctly different behavior compared with Al- and Nb-based transmons. They conclude that the temperature-dependent behavior of the neighboring charge-configuration transitions is caused by jumps between local charge configurations in the immediate vicinity of the transmon. This is in contrast to Al- and Nb-based transmons which are dominated by a TLS distribution giving rise to $1/f$ noise, apparently ruling out a TLS collection as the basis of the quasistable charge offsets in Ta-based transmons.

Very different types of superconducting devices are semiconductor–superconductor hybrid structures containing Andreev bound states (ABS) (Wendin and Shumeiko, 2022) and topological MZMs (Das Sarma et al., 2015; Pikulin et al., 2021; Aghaee et al., 2022). Recently Pikulin et al. (2021) developed an experimental protocol (Topological Gap Protocol, TGP) to determine the presence and extent of a topological phase with MZMs in a hybrid semiconductor–superconductor three-terminal device with two normal leads and one superconducting lead. Now Aghaee et al. (2022) have presented measurements and simulations of InAs-Al hybrid three-terminal devices that are consistent with the observation of topological superconductivity and MZM, passing the TGP. Passing the protocol indicates a high probability of detection of a topological phase hosting MZMs as determined by large-scale disorder simulations and is a prerequisite for experiments involving fusion and braiding of MZMs.

Hybrid distributed computing

In Section “HPC-centric approach” we talked about distributed quantum processing, running many QPU modules in parallel. It is a matter of debate whether future large-scale algorithms can be run on monolithic or modular QPUs fitting inside a single fridge, or whether the algorithms have to be distributed over several fridges and locations. Eventually one will be able to work with clusters of quantum computers connected via local or global quantum networks, but for now this represents a great challenge waiting for great breakthroughs and a quantum infrastructure.

On a smaller scale, recent work has connected superconducting qubit circuits between two separate chips linked by a microwave cable: Wallraff’s group (Magnard et al., 2020) produced multiqubit entanglement between single transmons in separate fridges while Cleland’s group (Zhong et al., 2021; Yan et al., 2022) demonstrated entanglement, purification, and protection between two separately enclosed three-transmon nodes inside the same fridge. The microwave connections are photonic, but limited to local clusters. The needed interfaces for long-distance optical connections are emerging (Chu and Gröblacher, 2020), but will probably remain research endeavors for quite some time (Arnold et al., 2020; Wang et al., 2022a; Kumar et al., 2022; Tsuchimoto et al., 2022).

On a larger scale, Ang et al. (2022) have developed architectures for superconducting modular, distributed, or multinode quantum computers (MNQCs), employing a “co-design”-inspired approach to quantify overall MNQC performance in terms of hardware models of internode links, entanglement distillation, and local architecture. In the particular case of superconducting MNQCs with microwave-to-optical interconnects, Ang et al. (2022) describe how compilers and software should optimize the balance between local gates and internode gates, discuss when noisy quantum internode links have an advantage over purely classical links, and introduce a research roadmap for the realization of early MNQCs. This roadmap illustrates potential improvements to the hardware and software of MNQCs and outlines criteria for evaluating the improvement landscape, from progress in entanglement generation to the use of quantum memory in entanglement distillation and dedicated algorithms such as distributed quantum phase estimation.

As a concrete example, DiAdamo et al. (2021) consider an approach for distributing the VQE algorithm over distributed quantum computers with arbitrary number of qubits in a systematic approach to generate distributed quantum circuits for QC. This includes a proposal for software-based system for controlling quantum systems at the various classical and quantum hardware levels. DiAdamo et al. (2021) emphasize that much effort has gone into distributed computing in the classical computing domain. And since the overlap between the fields is high, one can use this knowledge to design robust and secure distributed quantum computers, and as quantum technologies improve, this may become a reality.

Continuous variables—Computing with resonators

In this field, the resonator modes are the logical qubits, and the transmon qubits provide ancillas for loading and readout. The Yale group is leading the development, and has recently demonstrated some decisive breakthroughs (Sivak et al., 2022b). The name of the game is to construct logical qubits from linear combinations of (already long-lived) resonator states representing the Gottesman-Kitaev-Preskill (GKP) bosonic code, encoding a logical qubit into grid states of an oscillator. Sivak et al. (2022b) demonstrate a fully stabilized and error-corrected logical qubit whose quantum coherence is significantly longer than that of all the imperfect quantum components involved in the QEC process, beating the best of them with a coherence gain of $G \approx 2.3$. This was achieved by combining innovations in several domains including the fabrication of superconducting quantum circuits and model-free reinforcement learning (Sivak et al., 2022a).

To correct for single-photon loss, Kudra et al. (2022) have implemented two photon transitions that excite the cavity and the qubit at the same time. The additional degree of freedom of the qubit makes it possible to implement a coherent, unidirectional mapping between spaces of opposite photon parity. The successful experimental implementation, when supplemented with qubit reset, is suitable for autonomous QEC in bosonic systems, opening up the possibility to realize a range of nonunitary transformations on a bosonic mode.

For full-scale QEC, various groups have recently investigated the concatenation of CV and DV codes, such as concatenating the single-mode GKP code with the surface code. Instead, Guillaud and Mirrahimi (2019) present a 1D repetition code based on a cat code as the base qubit for which the noise structure is modified in such a way that QEC becomes of similar complexity as classical error correction and can be performed using a simple repetition code. According to Guillaud and Mirrahimi (2019), the specific noise structure can be preserved for a set of fundamental operations which at the level of the repetition code lead to a universal set of protected logical gates.

Regarding scaling up CV resonator technology, Axline et al. (2018) have experimentally realized on-demand, high-fidelity state transfer and entanglement between two isolated superconducting cavity quantum memories. By transferring states in a multiphoton encoding, they show that the use of cavity memories and state-independent transfer creates the striking opportunity to deterministically mitigate transmission loss with QEC. The results establish a basis for deterministic quantum communication across networks, and will enable modular scaling of CV superconducting quantum circuits.

The size of superconducting 3D microwave resonators makes it challenging to scale up large 3D multiqubit CV systems. An alternative may be provided by nanomechanical phononic nanostructures (Chu and Gröblacher, 2020). Chu et al. (2017) experimentally demonstrated strong coupling between a superconducting transmon qubit and the long-lived longitudinal phonon modes of a high-overtone bulk acoustic wave disk resonator (HBAR) formed in thin-film aluminum nitride (AlN). Recently, von

Lüpke et al. (2022) demonstrated HBAR parity measurement in the strong dispersive regime of circuit quantum acoustodynamics, providing basic building blocks for constructing acoustic quantum memories and processors. Moreover, Schirinski et al. (2022) measured long-lived HBAR Wigner states, monitoring the gradual decay of negativities over tens of microseconds. Wollack et al. (2022) use a superconducting transmon qubit to control and read out the quantum state of a pair of nanomechanical resonators made from thin-film lithium niobate (LN). The device is capable of fast swap operations, used to deterministically manipulate the nonclassical and entangled mechanical quantum states. This creates potential for feedback-based operation of quantum acoustic processors. Finally, Chamberland et al. (2022) have presented a comprehensive architectural analysis for a proposed fault-tolerant quantum computer based on cat codes concatenated with outer quantum error-correcting codes applied to a system of acoustic resonators coupled to superconducting circuits with a two-dimensional layout.

Biochemistry and life science—Drivers of quantum computing?

Biochemistry and life science are, as always, at the focus of high-performance computing, driving the development of exascale and postexascale supercomputers, experiencing the limitations and bottlenecks. These are topics and areas that would profit immensely from quantum advantage. As already mentioned, Reiher et al. (2017) practically created the vision of quantum chemistry as the killer application for quantum computers, needed to design new catalysts for efficient biochemistry, beyond the reach of classical computers. Since then, if not before, quantum chemistry and materials science present a kind of mission for QC to benchmark methods, algorithms, and computers (Santagati et al., 2023; Rubin et al., 2023; Babbush et al., 2023; O'Brien et al., 2022; Liu et al., 2022; Lee et al., 2022; Goings et al., 2022; Cheng et al., 2020).

In computational science there is the well-established method of multiscale modeling (Fish et al., 2021) that gave the Nobel Prize in Chemistry in 2014 to Arieh Warshel for modeling biological functions, from enzymes to molecular machines (Warshel, 2014). Multiscale modeling describes methods that simulate continuum-scale behavior using information derived from computational models of finer scales in the system, down to molecular quantum levels, bridging across multiple length and time scales. It is then natural to consider using a quantum computer to address the case of a quantum system embedded in a multiscale environment. Cheng et al. (2020) review these methods and propose the embedding approach as a method for describing complex biochemical systems, with the parts treated at different levels of theory and computed with hybrid classical and quantum algorithms.

Considering healthcare, life science, and artificial intelligence in a broad sense, from the huge databases of cell biology and human diseases, one can design network models describing the networks of Life. In particular Barabasi, Loscalzo, and collaborators (Barabasi et al., 2011; Lee and Loscalzo, 2019) developed the science of network medicine, and machine learning is essential for creating models for therapies that can design and control the action of drugs (de Siqueira Santos et al., 2022; Infante et al., 2021).

Maniscalco et al. (2022) recently published a forward-looking white paper: “Quantum network medicine: rethinking medicine with network science and quantum algorithms,” and posit that QC may be a key ingredient in enabling the full potential of network medicine, laying the foundations of a new era of disease mechanism, prevention, and treatment. This challenging vision reflects the mission of the entire field of QC—to achieve the elusive Quantum Advantage. The difficulty is amply illustrated by Goings et al. (2022) who discussed the ways to “explore the quantum computation and classical computation resources required to assess the electronic structure of cytochrome P450 enzymes (CYPs) and thus define a classical-quantum advantage boundary.” One conclusion (Goings et al., 2022) is that a large classically intractable CYP model simulation may need 5 million qubits and nearly 10 billion Toffoli gates, and may take 100 QPU hours. Another, less surprising, conclusion is that deep classical chemical insight is essential for guiding quantum algorithms and defining the computational frontier for chemistry.

Conclusion

Quantum computers and QC have evolved in ways that seemed almost impossible a few decades ago. When David DiVincenzo published his famous seven points stating the conditions for creating functional quantum computers (DiVincenzo, 2000), the first superconducting solid-state qubit had just been born (Nakamura et al., 1999). And 10 years later, demonstrating elementary operations on two-three superconducting transmon qubits still represented the state of the art in that field. Scaling to larger systems was not meaningful until the quality of qubits and the technology of electronic and optical control systems for driving and reading out qubits had improved. However, during the following 10 years, the telecommunication development has provided many of the tools needed, and some areas of the field have gone from academic science to engineering.

Strictly speaking, the current technology for quantum computers is nevertheless not yet scalable. Classical digital computers became scalable when high-quality integrated transistor circuits were combined with error correction in the 1960s—then the road was open toward scaling, as manifested by Moore’s Law (Moore, 1965). Moreover, the subsequent invention of microprocessors in the 1970s opened up the landscape for classical computers. Nevertheless it took 60 years to get to where we are now, in continuous mutual adaptation of problem solving and technology development. This has led to exascale supercomputers with currently ten million cores that still uphold Moore’s Law when it comes to computing power. However, as Landauer (May, 1991) pointed out, information is physical, which explains the current explosion of electrical power consumption for computing.

That long timescale is very different from today’s visions of what QC will be able to do already in a not-so-distant future, and certainly different from the mission of several academic and industry projects to deliver useful quantum advantage by the end of this

decade. Fortunately there are very few problems of importance to mankind that rely on the imminent arrival of quantum computers with quantum advantage. This is not to say that we do not need still more powerful computers—the problem is that the complex problems we may urgently want to solve, like the evolution of global climate dynamics, are NP-hard and can only be solved approximately, even by quantum computers. This means that predictions over time are necessarily uncertain. Adding to this the necessarily incomplete knowledge of models and background information, computation of our future unavoidably has huge error bars—uncertain predictions of the effects of global warming around the year 2100 are just one aspect of that.

The advantage of digital quantum computers beyond classical computing and algorithms must be established by benchmarking performance in practical applications. A common view in the HPC community is to regard QPUs as a kind of GPUs, closely integrated with the HPC and expected to accelerate the CPUs when handling hard problems that present classical bottlenecks. The development of HPC+QC integration is happening right now, and during the next 5 years, it will be taken to high levels—IBM is one prominent example. For sure this will challenge and boost the development of competitive classical algorithms and dedicated hardware—but useful quantum advantage for digital quantum computers may remain problematic in the NISQ era. It is therefore desirable to dampen some of the hype and promote realistic views of the near-future power of quantum computers. Industry currently involved in testing QC is certainly aware of what to expect, but that is not obvious when it comes to journalists and the public.

In the near term, the most important use of quantum processors may actually be to follow Feynman's original idea and create quantum hardware platforms for emulating physical systems with properties that are hard to describe by classical computers.

An important use of HPC is to make virtual rather than real-life experiments. One example is to describe the liquid environment of molecules via molecular dynamics simulations (Warshel, 2014). Another example is simulation of the behavior of aircraft in wind tunnels through extensive hydrodynamics calculations without need for real wind tunnels. In the same spirit, quantum processors already provide platforms for performing computer experiments, simulating fundamental quantum physics problems that are hard or impossible, in practice, for classical computers to describe. There are already impressive results for ion traps (Kokail et al., 2019, 2021), arrays of atoms (Scholl et al., 2021; Daley et al., 2022), and superconducting transmon processors (Arute et al., 2020b; Neill et al., 2021; Gong et al., 2021; Mi et al., 2022b; Zhang et al., 2022b; Karamlou et al., 2022; Landsman et al., 2019; Touil and Deffner, 2020; Mi et al., 2021; Braumüller et al., 2022; Mi et al., 2022a; Frey and Rachel, 2022; Kim et al., 2023). The near-term mission for superconducting processors might therefore be to emulate basic and applied physics experiments by mapping them on large superconducting controllable multiqubit networks that are impossible for classical digital supercomputers to simulate.

The next assessment of the future of quantum information processing is planned for 2028 (Wendin, 2028) and then we can perhaps compare notes.

Abstract

The topological model for quantum computation is an inherently fault-tolerant model built on anyons in topological phases of matter. A key role is played by the braid group, and in this survey we focus on a selection of ways that the mathematical study of braids is crucial for the theory. We provide some brief historical context as well, emphasizing ways that braiding appears in physical contexts. We also briefly discuss the 3-dimensional generalization of braiding: motions of knots.

Introduction

Quantum computation is predicated upon the ability to create, manipulate and measure the states in quantum systems (Freedman et al., 2003). In the topological model for quantum computation (Freedman et al., 2003; Nayak et al., 2008) the quantum systems of interest are topological phases of matter. Typically, these are 2 dimensional systems harboring point-like excitations—anyons (Wilczek, 1990). This alternative to the more traditional quantum circuit model is theoretically robust against decoherence due to the topological nature of the states: the information is stable due to invariance of the states under small, local perturbations. On the other hand, in order to implement quantum gates more drastic evolution of the states must be employed. The most natural choice is particle exchange of the anyons, so that their trajectories in $2 + 1$ dimensional space-time form braids. The corresponding transformations are the quantum gates, which are mathematically encoded in unitary representations of the braid group. The process of creating anyons, braiding them and then measuring form knots or links in $(2 + 1)$ -dimensional spacetime, which is interpreted as a (single run) of a topological quantum computation as illustrated in Fig. 1. Notice that the motions of the point-like excitations in the effectively two dimensional medium have a natural mathematical interpretation as the group of braids. Thus it comes as no surprise that the braid group $\mathcal{B}_n$ plays an outsized role in the development of topological quantum computation. In this article we will describe a selection of topics illustrating the connection between braids and topological quantum computation as well as some generalizations. We make no attempt to be exhaustive on the subject, nor will we provide a completely self-contained background. There are a number of much more complete treatments of topological quantum computation from various perspectives and for various tastes, a few of which we list here: (Wang, 2006, 2013, 2010; Delaney et al., 2016; Nayak et al., 2008; Pachos, 2012; Ogburn and Preskill, 1999; Freedman et al., 2003; Rowell, 2016; Rowell and Wang, 2018). For deeper and more complete mathematical details on the braid group and invariants of knots and links we suggest (Kassel and Turaev, 2008), while for the categorical background the text (Etingof et al., 2015) is an excellent resource. We provide a very brief tour of categorical notions in Appendix A.

Objectives

In the article we will:

- Introduce braids and the braid group, briefly discussing the history of braids in physics.
- Introduce topological quantum computation through a historical perspective.

Fig. 1 A single iteration of a topological quantum computation via braiding.

- Discuss the categorical model for the relevant topological phases of matter.
- Elucidate the role of the braid group in topological quantum computation through a series of examples.
- Give a higher dimensional generalization of the braid group and speculate on its relevance to topological quantum computation.

The braid group

The braid group $\mathcal{B}_n$ on n strands is most concisely described using the abstract group presentation by generators and relations due to Artin (Artin, 1925):

$$\mathcal{B}_n = \langle \sigma_1, \sigma_2, \dots, \sigma_{n-1} \mid \sigma_i \sigma_j = \sigma_j \sigma_i \text{ for } |i-j| \geq 2, \\ \sigma_i \sigma_{i+1} \sigma_i = \sigma_{i+1} \sigma_i \sigma_{i+1}, \text{ for } 1 \leq i, j \leq n-1 \rangle$$

The first relation is referred to as far commutativity and the second is the braid relation.

For visualization purposes we display the generator σ_1 and its inverse σ_1^{-1} geometrically as members of $\mathcal{B}_4$:

$$\sigma_1 = \begin{array}{c} \diagup \quad \diagdown \\ \diagdown \quad \diagup \end{array} \quad \sigma_1^{-1} = \begin{array}{c} \diagdown \quad \diagup \\ \diagup \quad \diagdown \end{array}$$

The composition in the group then corresponds to stacking, whereas the identity is clearly represented by unbraided strands.

Predating Artin's work on braids by 30 years is the work of Hurwitz (1891) on motions of points on the 2-dimensional sphere. This is much closer to their use in condensed matter physics: the world-lines of anyons under particle exchange can be viewed as trajectories of motions of points in the disk D^2 . Connecting braids to knots and links are two key mathematical results: Alexander's theorem (Alexander, 1923) and Markov's theorem (Markov, 1936). The key consequence of Alexander's theorem is that any knot/link may be obtained the plat closure: capping off the strands of a braid in $\mathcal{B}_{2n}$ pairwise, on both the top and bottom. Birman's (1976) analogue of Markov's theorem establishes a way to determine if two distinct braids have the same plat closure.¹

Braids and knots in physics: An incomplete history

Around the 7th century B.C.E. there was a debate between the natural philosopher Gārgī Vāchaknavī (daughter of Vachaknu) and the sage Yajñavalkya (Olivelle, 1998). She asks him:

Since this whole world is woven back and forth on water, on what then is it woven back and forth?

To which he replies "On air, Gārgī." The exchange continues with Gārgī asking what air and the intermediate regions are woven upon, and eventually what the universe is woven upon. This could be the most ancient reference to braids in physics. That the universe consists of a sequence of braidings may seem quaint by today's scientific standards, but the similitude with topological quantum circuits is nonetheless intriguing.²

Many point to Gauss as the first person to study knots mathematically and suggest he was inspired by physical considerations such as magnetic potential, see, e.g., (Epple, 1998; Przytycki, 1998; Ricca and Nipoti, 2011). Maxwell himself (Maxwell, 1873)

¹Both Alexander's and Markov's theorems actually deal with a different closure in which one glues the ends of top strands to the bottom strands. But the plat closure is more physically relevant.

²We thank Paul Martin for informing us of this ancient reference.

mentions Gauss' integral formula for the linking number of a two component link and its physical interpretation in electromagnetic induction.³ Gauss' interest in braids goes back even earlier according to Epple (1998), as he drew the following braid sometime between 1815 and 1830:

One might naturally surmise that Gauss' early interest in braids and knots were influential in his discovery of the linking number.

Yet another connection between physics and knots came some years later (see (Silver, 2014) for a full account) when Thompson (Lord Kelvin) learned of some experiments of Helmholtz in the 1850s producing knotted vortices of smoke. This led to the speculation by Thompson that matter was made up of knotted loops of luminiferous æther. This short-lived "vortex-atoms" theory suggested that different elements were distinguished by their knot-type. Yet again, we find an archaic theory resonating with a modern idea: in topological quantum computation information is stored in knotted world-lines of anyons. Mathematics reaped the benefit, as Tait produced the first reasonably comprehensive table of knots with few crossings, inspired by his friend Thompson's vortex-atom theory.

Topological quantum computation

Here we provide a historical perspective on topological quantum computation and set up the mathematical framework in terms of categories.

The origins of topological quantum computation

Topological quantum computation emerged as a confluence of ideas of Freedman, in topology, and Kitaev, in physics, (Freedman, 1998; Yu Kitaev, 2003) in the late 1990s. The framework was then laid out quickly in a series of papers of Freedman, Kitaev, Wang and Larsen (Freedman et al., 2002b,a, 2003).

Freedman postulated that physical systems described by topological quantum field theories (TQFTs) (Witten, 1989) could potentially be employed to perform certain Jones polynomial (Jones, 1985) evaluations. The Jones polynomial is a remarkably powerful invariant of knots and links. Its discovery in the early 1980s (Jones, 1985) precipitated the field of quantum topology. Although it is straightforward to compute for a given knot, the complexity of the computation grows quickly with the number of crossings. Indeed, evaluating the Jones polynomial at roots of unity is classically a #P-hard computation at most values (Jaeger et al., 1990). A clue to how physics could be useful for such computations is found in the original formulation of the Jones polynomial as the trace of the braid group representation associated with the $SU(2)$ Chern-Simons/Reshetikhin-Turaev TQFTs.

Meanwhile, Kitaev was interested in topological phases of matter harboring anyons for their potential use in fault-tolerant quantum computation. Topological phases of matter were studied going back to the 1970s and 1980s by the recipients of the 2016 Nobel Prize in Physics (Nobel Prize Committee, 2016): Kosterlitz, Thouless, and Haldane. Well-studied examples of include the fractional quantum Hall liquids (Moore and Read, 1991; Wen, 1991) that are expected to yield non-abelian anyons. Further examples include topological insulators (Nayak et al., 2008; das Sarma et al., 2015). More recently nanowires have been studied for their potential for harboring anyons (Mourik et al., 2012; Albrecht et al., 2016). The need for expensive error-correction due to decoherence continues to be a major hurdle for scaled up quantum computation. Kitaev's idea was that quantum gates could be implemented by braiding anyons, so that error-correction comes from the topological nature of the systems.

Remarkably, Freedman's and Kitaev's proposals are two sides of the same coin: 2D topological phases of matter are modeled by TQFTs! It is a rare instance when two essentially independent ideas converge yielding a powerful new paradigm.

To breathe life into this new paradigm some deep mathematics was needed from both quantum topology and group theory. The resulting proof-of-principle of topological quantum computation is found in Freedman et al. (2002b), Freedman et al. (2002a). There they show that (1) the topological model for quantum computation could be as powerful as the more standard quantum circuit model based on qubits and (2) it is not more powerful than the quantum circuit model. The second result is proved by showing that any topological quantum computation can be simulated on a universal qubit machine with polynomial overhead. The first result show that universal topological quantum computers exist, in principle. We will return to this below.

³There is some historical controversy here, which the reader may find in the references.

Modeling topological phases with categories

Anyons are topological quantum fields emerging as finite energy particle-like excitations in topological phases of matter. Like particles, they can be moved, but cannot be created or destroyed locally. To model them we consider the fusion and braiding structures of these elementary excitations in the plane. The anyon system is then modeled by a *unitary modular category* (UMC). For this reason we will use *anyon model* and *unitary modular category* synonymously.

There is a philosophical explanation for why category theory is suitable for describing some quantum physics. In quantum physics we appeal to measurements to “see” the elementary particles by analyzing their responses to measuring devices. Anyons are *defined* by how they interact with other particles, and their responses to measuring devices. According to [Kapranov and Voevodsky \(1994\)](#), the main principle in category theory is: “In any category it is unnatural and undesirable to speak about equality of two objects.” In category theory an object X is determined by the vector spaces of morphisms $\text{Hom}(X, Y)$ for all Y in the tensor category. Therefore, it is natural to treat objects as anyons, and the morphisms as models of the quantum processes between them. For a more complete treatment see the survey ([Rowell and Wang, 2018](#)).⁴ The notion of a modular tensor category was invented by Moore and Seiberg using tensors ([Moore and Seiberg, 1989](#)), and its coordinate-free version: *modular category* was defined by [Turaev \(1992\)](#). In this model, an anyon X is a simple object in the category, while the vacuum is regarded as the monoidal unit 1 . The Hilbert space of states of a system of anyons on a disk with prescribed boundary condition is modeled by the space of morphisms in the category so that the braiding of anyons provides unitary operators as the system evolves: the quantum gates in topological quantum computation. For example, the Hilbert space associated with n indistinguishable X anyons in the disk with boundary condition (total charge) Y is the space $\text{Hom}(Y, X^{\otimes n})$. One assumption is that there are finitely many distinguishable indecomposable anyon types (including the vacuum type): $\{X_0 = 1, X_1, \dots, X_r\}$, so that that every anyon corresponds to some fixed type $a \in \{0, \dots, r\}$. A dictionary of terminologies between categories and anyons systems is given in [Table 1](#), adapted from [Wang \(2010\)](#). The Hilbert space $V_{ab}^c = \text{Hom}(a \otimes b, c)$ represents the span of the linearly independent ways of fusing anyons of type a and b to obtain the anyon of type c . In topological phases of matter the *ground state degeneracy* is typically encoded as the dimension of the spaces $\bigoplus_c V_{ab}^c$ where the sum is over all anyon types c . Most often this is consider for $a = b$ so that we can speak of the ground state degeneracy of a given anyon. In the vernacular one says a has non-trivial ground-state degeneracy if $\dim(\bigoplus_c V_{aa}^c) > 1$.

There are two basic local events that can occur during a topological quantum computation besides braiding, namely *splitting* and *fusion*. Fusion is when two anyons combine to produce another anyon, while splitting is the reverse. These events are conveniently represented using the diagrams in [Fig. 2](#). A special case of fusion is *annihilation* when an anyon particle and its anti-particle fuse to the vacuum. Similarly *creation* is a special case of splitting in which a particle/anti-particle pair are drawn from the vacuum. We often depict the splitting/fusion involving the vacuum anyon type 1 by a dotted line, or sometimes we omit it entirely. This is justified as the vacuum anyon may be freely inserted/deleted in the system. Braiding is the isomorphism denoted $c_{X,Y} : X \otimes Y \mapsto Y \otimes X$.

As there are finitely many anyon types one may encode the fusion rules into a matrix: for a fixed type a , define $[N_a]_{c,b} := \dim(V_{ab}^c)$. Running over all pairs (b, c) we obtain the fusion matrix N_a . An important invariant of an anyon is the *dimension* d_a of the corresponding anyon type: this is simply the largest eigenvalue of N_a , which is guaranteed to be real and positive by the Perron-Frobenius theorem. However, this dimension is not necessarily an integer—in general it is a real cyclotomic integer: a real number that can be expressed as a finite sum of roots of unity. We shall see later that the computational utility of anyons of type a in a given system is intimately intertwined with the value of d_a .

Table 1 A dictionary of categorical terms and their interpretations in anyonic systems.

Anyon model (UMC)	Anyonic system
Simple object	Anyon
Label	Anyon type or topological charge
Tensor product	Fusion
Triangular space V_{ab}^c or V_c^{ab}	Fusion/splitting space
Dual	Antiparticle
Birth/death	Creation/annihilation
Braid representation	Anyon statistics
Morphism	Physical process or operator
Braids	Anyon trajectories

Fig. 2 Basic local events: fusion, splitting and braiding.

⁴We shall not need a full treatment here, we will introduce the key ideas as they become necessary.

We are now ready to describe the braid group representations associated with anyons of type a in a topological phase of matter. Suppose we have n type a anyons localized at positions $1, \dots, n$ in the system, whose total charge is b . Interchanging the anyons at positions i and $i+1$ induces a unitary operator $U_i(b)$ on the state space $\mathcal{H}(b; a, \dots, a) = \text{Hom}(b, a^{\otimes n})$, which represents the braid group generator σ_i . Extending to all such interchanges and summing over all possible boundary conditions we obtain a representation

$$\rho_a : \mathcal{B}_n \rightarrow U\left(\bigoplus_b \mathcal{H}(b; a, \dots, a)\right) \quad \text{via} \quad \sigma_i \mapsto \bigoplus_b U_i(b).$$

With this formulation in hand, we can mathematically analyze topological gates. Note that dimension of the representation $\bigoplus_b \mathcal{H}(b; a, \dots, a)$ is asymptotic to d_a^n , so that the ground state degeneracy of n type a anyons in the disk can be approximated using the quantum dimension.

It is useful to keep in mind three examples: (1) the Fibonacci anyon τ with fusion rule $\tau^{\otimes 2} = 1 + \tau$ and quantum dimension $d_\tau = \frac{1+\sqrt{5}}{2}$ (2) the Ising anyon σ with fusion rules $\sigma^{\otimes 2} = 1 + \psi$, $\psi \otimes \sigma = \sigma$, and $\phi^{\otimes 2} = 1$ with $d_\sigma = \sqrt{2}$ and (3) the $\mathbb{Z}/3$ anyon ω with fusion rules $\omega^{\otimes 2} = \omega^*$, $\omega \otimes \omega^* = 1$ and $d_\omega = 1$. The ground state degeneracy of Fibonacci anyons in a disk is a Fibonacci number, while the $\mathbb{Z}/3$ has no disk ground state degeneracy and the Ising theory has disk ground state degeneracy of the form 2^n .

The role of the braid group in TQC

In this section we will review a number of ways that the braid group plays an essential role in topological quantum computation. The examples presented here are representative of the author's tastes and are by no means exhaustive.

Detecting non-abelian anyons via braiding

If the braid group representation ρ_a associated with an anyon of type a has abelian image, we say that a is an *abelian* anyon. Abelian anyons have been convincingly demonstrated in the laboratory, and can even be directly shown to admit braidings (Nakamura et al., 2020). Notice that anyons that have no ground state degeneracy are automatically abelian: if $\dim(V_{aa}^c) = 1$ for a *unique* anyon type c then it can be shown that $\text{Hom}(b, a^{\otimes n})$ is 1-dimensional for a unique type b for each n , and 0-dimensional for all other types $c \neq b$. Thus the braid group representation ρ_a described above is 1 dimensional, hence has abelian image. In particular if $d_a = 1$, then a is an abelian anyon. On the other hand, non-abelian anyons are essential if one is to have any interesting (i.e., not phases) braiding gates. How can one detect if an anyon is non-abelian? In Rowell and Wang (2016) it is shown that if a is abelian then necessarily $d_a = 1$. The idea is the following where we assume that a is its own anti-particle type for convenience⁵:

Suppose that an anyon X of type a has $d_a > 1$, yet is abelian. This implies that there is some anyon Y of non-vacuum type $b \neq 1$ so that $\dim(V_{aa}^b) \geq 1$ by a simple eigenvector argument. We construct a non-zero state in $\text{Hom}(a, a^{\otimes 3})$ by drawing a pair of type a anyons out of the vacuum (we have assumed that the splitting space $\text{Hom}(1, a^{\otimes 2})$ is non-trivial). Next we perform the braiding $\sigma_1 \sigma_2 \sigma_1^{-1} \sigma_2^{-1} \in \mathcal{B}_3$ on this state. Now $a^{\otimes 2}$ decomposes as a sum of simple objects that includes b , so that there is a non-zero vector in $\text{Hom}(a, b \otimes a)$, which can be achieved as a consequence of a fusion of the left two type a anyons to a type b anyon Y . So the process yields the state in Fig. 3. Now if the X anyon were abelian, then the image of the braid $\sigma_1 \sigma_2 \sigma_1^{-1} \sigma_2^{-1}$ must be the identity, as illustrated in Fig. 4. Thus, since we cannot create a single anyon out of the vacuum, we obtain the zero state as illustrated in Fig. 5. This contradicts the assumption that $d_a > 1$.

Computing the quantum dimensions of the Fibonacci, Ising and $\mathbb{Z}/3$ anyons we get $\frac{1+\sqrt{5}}{2}$, $\sqrt{2}$ and 1, respectively. Thus the Fibonacci and Ising anyons are non-abelian, while the $\mathbb{Z}/3$ anyons are abelian.

Fig. 3 A state achieved by creating a pair of X anyons from the vacuum, braiding, and then fusing two X anyons to an anyon Y . This is a non-zero state.

⁵This is not a crucial restriction: a slightly more complicated argument works for all types and in most examples one hopes to construct in the laboratory this is satisfied anyway.

Fig. 4 If X is abelian, the sequence of braids has the same effect as the identity braid.

Fig. 5 Since $Y \neq \mathbf{1}$, the state on the left must be zero, and therefore the whole state must be 0.

Braiding universality

The foundational paper (Freedman et al., 2002b) exhibited the theoretical viability of topological quantum computers by showing that the so-called Fibonacci anyons are universal for quantum computation. This was achieved by demonstrating that one could efficiently approximately simulate a universal qubit computer on the Fibonacci topological model. Let us briefly recall the qubit model (Nielsen and Chuang, 2000). A qubit is a 2-dimensional vector space $V = \mathbb{C}^2$, typically modeled by some 2-level quantum system, e.g., a spin-system. One fixes a gate set $\mathcal{G}$ consisting of unitary operators $U_i \in U(V^{\otimes n_i})$. N -qubit quantum circuits are built as compositions of promotions of the U_i to $V^{\otimes N}$, i.e., $I_V^{\otimes a} \otimes U_i \otimes I_V^{\otimes b}$ where $N = a + n_i + b$. Each application of a gate is considered a single step, hence the length of the quantum circuit in an algorithm represents consumed time, and is a complexity measure. A gate set should be physically realizable and complicated enough to perform any computation given enough time.

Definition 3.1: The gate set $\mathcal{G}$ is said to be *universal* if any unitary operator $X \in U(V^{\otimes N})$ can be efficiently approximated (up to a phase) by a quantum circuit built from $\mathcal{G}$.

A typical choice of a universal gate set is

$$\mathcal{S} = \left\{ H, \sigma_z^{1/4}, \text{CNOT} \right\}$$

consisting of the Hadamard, $\pi/8$ and CNOT gates:

$$H = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}, \quad \sigma_z^{1/4} = \begin{pmatrix} 1 & 0 \\ 0 & e^{\pi i/4} \end{pmatrix}, \quad \text{CNOT} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix}$$

Here the efficiency should be that the length of the quantum circuit is a polynomial in the desired accuracy. The Kitaev-Solovay theorem (see Freedman et al., 2002b for the most appropriate formulation) states that it is enough to show that the closure of the N -qubit circuits in the operator norm topology contains all unitaries in $U(V^{\otimes N})$ up to phases.

For the topological model with gates obtained from braiding as above, the following is the equivalent formulation of universality:

Definition 3.2: An anyon X is called *braiding universal* if, for some n_0 , the images of $\mathcal{B}_n$ on the irreducible sub-representations $W \subset \text{End}(X^{\otimes n})$ are dense in $SU(W)$ for all $n \geq n_0$.

This is a mathematically precise definition, but in practice it can be quite difficult to verify universality (Freedman et al., 2002b). The Fibonacci anyon τ , which has quantum dimension $\frac{1+\sqrt{5}}{2}$ is universal, while the Ising anyon σ which has quantum dimension $\sqrt{2}$ is not. In fact the image of the braid group representations associated with the Ising anyon σ have *finite* groups as their images—very far from universal!

In practice this appears to be the dichotomy: either an anyon X is braiding universal, or the representations ρ_X have image a finite group, in which case we say X is a *property F* anyon. In principle, to determine if the image is finite or infinite requires fairly explicit descriptions of the representations, which are not always available. It would be useful to have an indirect way of detecting when an anyon X has associated braid group representations ρ_X with infinite image. The following gives a very concise conjectural condition:

Conjecture 3.1: (Naidu and Rowell, 2011) *An anyon X is braiding universal if and only if $d_X^2 \notin \mathbb{Z}$.*

For simplicity we are conflating “infinite image” with “universality.” But we do not lose too much by doing so: if an irreducible unitary braid group representation $\rho_X : \mathcal{B}_n \rightarrow U(V_n)$ has infinite image in $U(V_n)$ then its closure $\overline{\rho_X(\mathcal{B}_n)}$ is some infinite compact Lie group G . By analyzing the eigenvalues of the braid group generators’ images one finds that G contains, with few exceptions, $SU(V_n)$, $SO(V_n)$ or $Sp(V_n)$ (see Larsen et al., 2005 for the general method).⁶ To obtain universality on the nose one hopes for the first case, but one can typically lift the second two cases to special unitaries by taking n slightly larger.

This conjecture has been verified in numerous cases, see, e.g., (Etingof et al., 2008; Rowell, 2010; Rowell and Wenzl, 2017; Green and Nikshych, 2021; Larsen et al., 2005). In particular it is known to be true for anyon models obtained from quantum groups at roots of unity (equivalently, Kac-Moody algebras) as well as all so-called *weakly group-theoretical* braided fusion categories. This latter class includes the metaplectic anyons of Hastings et al. (2014).

Measurement assisted universality

Convincing laboratory confirmation of the existence of non-abelian anyons is still a major hurdle. The simplest model for non-abelian anyons correspond to the Ising categories, known as the Majorana zero modes (or more colloquially, Majorana fermions) (das Sarma et al., 2015). It would be a breakthrough to have such a confirmation for the Majorana zero modes. On the other hand, this could not be used for braiding universal topological quantum computation. The next simplest non-abelian anyons correspond to the $SU(2)_4$ model (certain metaplectic anyons (Hastings et al., 2014)), with some numerical evidence that this is realized by the fractional quantum Hall liquids at filling fraction $\nu = 8/3$ [PWC⁺15]. But again, these are not braiding universal. If nature conspires against us (which she so often does) it might be the case that braiding universal anyons are out of reach. While disappointing, this does not mean that one cannot have topological quantum computers. In Cui et al. (2015), Cui and Wang (2015) protocols for recovering universality from metaplectic anyons are presented. The idea is to produce a universal gates set from braiding gates and one non-braiding gate achieved through a projective measurement of topological charge.

Specifically, the system modeled by the $SU(2)_4$ includes anyons $1, Z, X$, and Y with the fusion rules $X^{\otimes 2} = 1 + Y$ and $Y^{\otimes 2} = 1 + Z + Y$, where Z is an abelian anyon satisfying $Z^{\otimes 2} = 1$ and $Z \otimes Y = Y$. A single qutrit is encoded as in Fig. 6.

The space is 3 dimensional, corresponding to the pairs (a, b) which can be $(1, Y)$, $(Y, 1)$, or (Y, Y) . While braiding the four X -type anyons provides many gates, braiding alone is not universal. The additional measurement that must be performed is a projection of the left two X -type anyons onto the vacuum 1 -type, and the orthogonal complement. If the left pair total charge is not 1 then the right pair total charge is in a coherent superposition of $(Y, 1)$ and (Y, Y) . This operation, together with the braiding gates is universal.

Distinguishing anyons and anyon systems via braiding

One of the key axioms of a modular category is the *non-degeneracy* of the braiding: this says that the only anyon type X so that the full exchange (double braid, see Fig. 7) with all anyon types Y is trivial is the vacuum type 1 .

This turns out to be equivalent to the condition that the matrix with entries $S_{ab} := \text{tr}(c_{a,b} \circ c_{b,a})$ for all pairs of anyon types (a, b) has $\det(S) \neq 0$ (Bruguières, 2000).

This implies that, in principle, one may distinguish anyons X and Y by performing all exchanges of X and Y with an anyon of each other type. One would of course need to perform measurements—in this case the right computation is essentially the one illustrated

Fig. 6 One qutrit from $SU(2)_4$.

Fig. 7 If the full exchange is trivial for all Y , anyon X is transparent.

⁶These are the special unitary, special orthogonal and symplectic Lie groups.

in Fig. 1, creating two particle/anti-particle pairs and then projecting onto the vacuum-vacuum state. These are precisely the entries of the matrix S , in diagrams:

The S -matrix entries are the invariants of the Hopf link, with components “colored” by pairs of anyon types. Thus the non-degeneracy condition implies we may distinguish anyons by the set of double braidings.

The S -matrix records the traces of all double braidings, and hence gives an invariant of the anyon model. Suppose we wish to pin down precisely which modular category is the model for our anyon system. What computations/measurements must one perform? The quantum dimension d_a of each anyon type appears in the S -matrix: it corresponds to setting $b = 1$. Another invariant is obtained by taking the trace of a single braiding of X with itself, see Fig. 8: this yields the quantity $d_X \theta_X$ for a root of unity θ_X , known as the *topological spin* of X .

The S -matrix together with the twists θ_a for all anyon types a form the *modular data* of the theory. Is the modular data enough to determine the anyon model? The answer turns out to be “no” (Mignard and Schauenburg, 2017). It is possible for two inequivalent anyon models to have exactly the same modular data: known as *modular isotopes* (Delaney et al., 2021). By the philosophy that the anyon model should be determined by the topological measurements (mathematically, invariants) one might expect that there is a finite set of measurements that would determine the theory. That is, one seeks a set of knots and links, including the modular data, so that the invariants one obtains by “coloring” the components by anyon types completely determines the anyon model.

The two component Whitehead link is one candidate (see Fig. 9, left) which together with the modular data can be used to distinguish some modular isotopes (Bonderson et al., 2019). The Whitehead link is named after the topologist J. C. Whitehead but predates him by about one millennium—it is found on Viking artifacts from around 1000 C.E (Fig. 9, right). Interestingly, the Whitehead link has Gauss linking number 0.

Beyond braids

In the Gārgī-Yajñavalkya debate one finds the suggestion that the cosmos are braids upon braids upon braids. Lord Kelvin, in his the vortex-atom theory, proposed that all matter is built from knots. From our modern perspective these ideas are easily dismissed, but we see glimmers of them in topological phases of matter. Is there more to this?

So far we have focused on braids as trajectories of point-like excitations with 2-dimensional ambient space, and have seen that the braid group plays a key role. Many interesting computational and physical questions can be answered by studying braids. Can we push this theory to higher dimensions? Point-like excitations in 3 dimensions are not interesting: they must be bosons or fermions, and are thus abelian in the sense that braiding them has abelian image. But what about other kinds of excitations, such as loop-like vortices? Or, for that matter, knot-like vortices? At least mathematically, we can describe the dynamics of system in which knots are braided! The simplest example is known as the *loop braid group*: the motions of n oriented circles in S^3 . It has two kinds of generators: the first by “leapfrogging” the i th circle through the $(i + 1)$ st σ_i and the second by loop interchanges s_i for $1 \leq i \leq n - 1$. This group is denoted $\mathcal{LB}_n$ and has only been studied relatively recently (see Damiani, 2017 for a survey). Abstractly, $\mathcal{LB}_n$ is the

$$c_{X,X} = \begin{array}{c} X \quad \quad X \\ \diagdown \quad \diagup \\ \diagup \quad \diagdown \\ X \quad \quad X \end{array}$$

Fig. 8 The braiding of X with itself: the trace of this operator has value $d_X \theta_X$.

Fig. 9 Left: A braid with closure the Whitehead link colored to emphasize components. Right: Thor's hammer (Mjölnir) artifact featuring the Whitehead link, dating from around 1000 C.E.

Fig. 10 The Necklace: motions include leapfrogging and moving each small circle by a rotation of $2\pi/n$ around the center point of the large circle.

Fig. 11 Three trefoils: distinct motions could include passing one such knot through any of the four holes in a neighboring knot.

group generated by one copy of the n -strand braid group (generated by the σ_i) and one copy of the symmetric group (generated by the s_i) with the additional (mixed) relations:

$$\sigma_i \sigma_{i+1} s_i = s_{i+1} \sigma_i \sigma_{i+1}, \quad s_i s_{i+1} \sigma_i = \sigma_{i+1} s_i s_{i+1}, \quad 1 \leq i \leq n-2, \quad \sigma_i s_j = s_j \sigma_i \quad \text{if } |i-j| > 1.$$

Other configurations are possible, such as “the necklace” as in Fig. 10. Representations of the motion group of the necklace, the *necklace braid group* have been studied, for example, in Bullivant et al. (2020).

A more complicated, but nonetheless intriguing example is the motions of three or more trefoil knots as in Fig. 11. One can imagine many different “leapfrog” motions between a pair of such knots.

Equipped with the mathematical description of these motions, one should be able to approach the theoretical analogues of those described above for 2-dimensional systems in topological phase, such as: *How do we model these systems?* and *What is the computational power of such a system?*

Conclusion

The landscape of topological quantum computation is still in flux as the goals of computer science and the realities of physics are reconciled within the bounds of engineering. It seems clear that on the mathematics side the braid group will continue to play a key role, with adjustments as dictated by the relevant models, as in the example of measurement-assisted universality. As new sources of quantum systems with topological features are found and our understanding of the extant systems is deepened, new ideas will be needed to find mathematical models and explore their utility in quantum technologies.

Appendix on categorical notions

We have used a number of standard notions from category theory that the reader may not be familiar with. Here we lay down some of the key ideas for the reader’s convenience, always deferring to Etingof et al. (2015) for a comprehensive treatment.

A *category* consists of a collection of *objects* $X, Y, \dots$ (not necessarily a set, and the objects have no assumed structure), together with a collection of *morphisms* $\text{Hom}(X, Y)$ for each pair of objects, with a distinguished element $\text{id}_X \in \text{Hom}(X, X) = \text{End}(X)$ for each object X . These morphisms can be composed when it makes sense to, and the composition is assumed to be associative. A basic idea in category theory is to axiomatize the notion of “sameness.” Two objects X, Y are said to be isomorphic if there are morphisms $f \in \text{Hom}(X, Y)$ and $g \in \text{Hom}(Y, X)$ so that $f \circ g = \text{id}_Y$ and $g \circ f = \text{id}_X$. It is worth pointing out that while the objects have no structure (nor do the collection of objects), the morphisms do have structure.

In modern category theory one adds additional *structures* and requires additional *properties*. It can often be confusing to distinguish between structures and properties, but typically there are choices for a structure, while a property is either satisfied or isn’t. For an instructive example from algebra, consider a set X with a binary operation $(x, y) \mapsto x \circ y \in X$. This is called a *magma* and it depends a structure—there are many choices for $\circ$. On the other hand, if the *property* that $(x \circ y) \circ z = x \circ (y \circ z)$ holds for all x, y, z then the magma $(X, \circ)$ is called a *semigroup*. If there is an element $e \in X$ so that $e \circ x = x \circ e = x$ for all x , this is an additional property and the semigroup is called a *monoid*. If the property that $x \circ y = y \circ x$ for all x, y the monoid is called commutative, or abelian. To be a group the monoid must satisfy another property: every element should have an inverse. We could continue to build structures and insist on properties: a commutative group with an additional structure of scalar multiplication by the real numbers $\mathbb{R}$ satisfying several more properties defines a vector space, and so on. We are often interested in classifying categories with certain

structures and properties. Moreover, many of the structures and properties are categorical generalizations of algebraic constructions we are already familiar with.

The categories we are concerned with are *modular categories*: concisely (albeit obfuscating), these are non-degenerate spherical braided fusion categories. Each of these adjectives carries with it some structure and/or assumes some properties hold. We will first unravel this definition in somewhat broad strokes before providing some examples.

- (1) *Fusion* categories are modeled after the category of finite-dimensional complex representations $\text{Rep}(G)$ for a finite group G . This axiomatizes notions like direct sum (additive structure), tensor product (monoidal structure $\otimes$) with proscribed associativity morphisms $\alpha_{X,Y,Z}$, trivial representation (monoidal unit 1), linearity ($\text{Hom}(X,Y)$ is a finite dimensional vector space), duality (objects V^* for each V), irreducibility (simple objects), finiteness (finitely many simple objects up to isomorphism, among which is 1), and semisimplicity (all objects are sums of simples). *Sphericity* is a somewhat technical property having to do with choices ("pivotal" structure) of isomorphisms $V \cong V^{**}$ that lead to a notion of left and right traces for morphisms. Essentially, this structure is spherical if the ensuing left and right traces coincide. This trace is used to define the S -matrix in Section 3.4 for example.
- (2) A *braiding* structure on a fusion category is a collection of morphisms $c_{X,Y} \in \text{Hom}(X \otimes Y, Y \otimes X)$ that satisfy a version of the braid equation. This is of course crucial for our exposition above: the key fact is that

$$\sigma_i \mapsto \text{id}_X^{\otimes i-1} \otimes c_{X,X} \otimes \text{id}_X^{\otimes n-i-1}$$

can be modified to a braid group representation after employing appropriate re-coupling of the tensor factors. In practice one often assumes the category is *strict* so that the associativity constraints are identities. In the presence of a braiding the spherical structure is encoded in the topological twists $\Theta_X \in \text{Hom}(X, X)$ for each object X . For simple objects we have $\Theta_X = \theta_X \cdot \text{id}_X$ where θ_X is a root of unity. They satisfy the *balancing equation*: $\Theta_{X \otimes Y} = c_{Y,X} c_{X,Y} \Theta_X \otimes \Theta_Y$ which allows one to represent morphisms as labeled ribbons and manipulate them in a topologically consistent way (*graphical calculus*).

- (3) The braiding has the property of being *non-degenerate* if the only simple object X such that $c_{Y,X} \circ c_{X,Y} = \text{id}_{X \otimes Y}$ for all Y is the monoidal unit 1 . For a fixed spherical structure non-degeneracy can be encoded in terms of the invertibility of the S -matrix.

Three examples to keep in mind are the categories *Fib*, *Ising* and $\mathcal{C}(\mathbb{Z}/3)$ alluded to above. You may find further details on these categories in Rowell et al. (2009), Section 5.3, in which modular categories with at most four simple objects are classified.

Example A.1: The category *Fib* has 2 simple objects 1 and τ with fusion rules $\tau \otimes \tau = \tau \oplus 1$ as mentioned in the main text. The S -matrix is $\begin{pmatrix} 1 & \varphi \\ \varphi & -1 \end{pmatrix}$ where $\varphi = \frac{1+\sqrt{5}}{2}$. The twist of τ is $\theta_\tau = e^{4\pi i/5}$, while $\theta_1 = 1$ (for any category, in fact). The anyon τ is universal. We have $\tau^* \cong \tau$ —the Fibonacci anyon is self-dual.

Example A.2: *Ising* has 3 simple objects 1 , ψ and σ with the fusion rules described in the main text. The S -matrix is $\begin{pmatrix} 1 & \sqrt{2} & 1 \\ \sqrt{2} & 0 & -\sqrt{2} \\ 1 & -\sqrt{2} & 1 \end{pmatrix}$ while the non-trivial twists are $\theta_\psi = -1$ and $\theta_\sigma = e^{\pi i/8}$. The object ψ is a mathematical *fermion*: it is an abelian anyon with twist -1 . The anyon σ is non-abelian, but non-universal. All of the objects in the *Ising* category are self-dual.

Example A.3: The category $\mathcal{C}(\mathbb{Z}/3)$ consists of abelian anyons 1 , ω , ω^* with the fusion rules like the group $\mathbb{Z}/3$. In this case the object ω is not self-dual as $\omega \not\cong \omega^*$. The S -matrix is $\begin{pmatrix} 1 & 1 & 1 \\ 1 & q & 1/q \\ 1 & 1/q & q \end{pmatrix}$ where $q = e^{2\pi i/3}$, and the twists are $\theta_\omega = \theta_{\omega^*} = q$.

We have introduced modular categories as a kind of axiomatization of various algebraic structures that some familiar categories have. Another perspective on modular categories is that it is the categorical structure underlying $(2+1)$ -dimensional topological quantum field theory. As a fundamental level then modular categories may be thought of as the categorification of ribbon diagrams: essentially the various diagrams one may draw using the basic events in Fig. 2, interpreted as morphisms in some category, so that composition is stacking and the labels represent a finite set of colors for the ribbons. While we have drawn the ribbons as curves, it should be emphasized that these really have some width and a "framing" which is essentially the number of times the ribbon is twisted along its axis. The modularity condition is natural in the sense that it says we may distinguish the colors by means of braiding and traces.

Abstract

The idea of topological quantum computation with non-abelian anyons is presented using Fibonacci anyons as the building blocks of topological qubits. Using a single qubit conventional quantum computer as a reference, we outline how braiding Fibonacci anyons may be used for realizing fault tolerant topological qubit operations. We mention some key issues affecting topological quantum computers, and conclude with a brief discussion on the future prospects of topological quantum computing.

Objectives

- To introduce the idea of topological quantum computation by using the Fibonacci anyon model as an exemplar.
- To mention certain technicalities that affect the efficacy of braid-based topological quantum computers.
- To embed the Fibonacci anyon model within the broader context of nonabelian anyons and topological quantum computers.

Introduction

The material world around us is composed of two kinds of elementary particles, the bosons and the fermions (Leggett, 2005). This observation is formalized by the spin-statistics theorem, which essentially states that upon transporting a particle around another indistinguishable particle, the quantum state describing these particles must either remain unchanged (bosons) or change its sign (fermions). This is related to the fact that such a world line path can be contracted to a point. However, in systems where the (quasi) particles are constrained to move in two-dimensional plane, the mutual quasiparticle exchange statistics does not need to be bosonic or fermionic but can in principle be anything in between (Leinaas and Myrheim, 1977). Such quasiparticles are called anyons (Wilczek, 1982). The essence of the topological difference between the three and two dimensional systems is illustrated in Fig. 1. The topological richness afforded by two dimensional systems allows for an even more exotic possibility where an encirclement of one quasiparticle by another one may cause such a quasiparticle to become transmuted into an entirely different kind of quasiparticle! Such quasiparticles are called non-abelian anyons and they could be used as building blocks for constructing a topological quantum computer. For a comprehensive technical introduction to the topic of this encyclopedia entry on Fibonacci anyon based topological quantum computation, we refer the reader to Nayak et al. (2008), Trebst et al. (2008), Lahtinen and Pachos (2017), Field and Simula (2018).

Overview

It is useful to briefly outline some key concepts of conventional quantum computation before discussing the basics of a topological quantum computer. Note that, in addition to conventional and braid based topological quantum computers, several other kinds of quantum computer models also exist, such as a measurement-based one-way quantum computer, that will not be discussed here.

Fig. 1 Illustration of an exchange of two bosonic or fermionic particles along a contractible path (left) and two anyon quasiparticles along a non-contractible path (right). In the former case the particles can be “lifted off the world line,” where as in the latter case this is not topologically allowed.

Fig. 2 Bloch sphere representation of single-qubit quantum computation. (a) the qubit is initialized in state $|0\rangle$. It is then rotated (dotted trajectory) using unitary quantum gates to the final superposition state $|\psi\rangle$. A projective measurement of the final state will yield the results $|0\rangle$ and $|1\rangle$ with probabilities $|\alpha|^2$ and $|\beta|^2$, respectively. (b) the initial state $|0\rangle$ is rotated using the Hadamard gate H to a final state $H|0\rangle$. A noisy Hadamard gate H' leads to a deviation in the state vector and such errors rapidly accumulate during quantum computation.

Conventional two-level quantum computer

The “transistor” of a conventional quantum computer is called a qubit or an artificial two-level atom. The qubit has two possible states

$$|0\rangle = |\uparrow\rangle = \begin{pmatrix} 1 \\ 0 \end{pmatrix} \text{ and } |1\rangle = |\downarrow\rangle = \begin{pmatrix} 0 \\ 1 \end{pmatrix} \quad (1)$$

referred to as the spin-up and spin-down, respectively.¹ An arbitrary single qubit state may be expressed as a superposition

$$|\psi\rangle = (|0\rangle + e^{i\theta}|1\rangle)/\sqrt{2} \quad (2)$$

of the two possible qubit eigenstates, where θ determines the azimuthal phase angle of the state vector, and every one of such states can be visualized by a state vector on the Bloch sphere, shown in Fig. 2.² The state vectors can be rotated using unitary quantum gate operators U such as the Hadamard gate

$$H = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix} \quad (3)$$

to yield new state vectors $|\psi\rangle = U|\psi_0\rangle$ from the initial states $|\psi_0\rangle$. Quantum computation corresponds to sequential application of a predetermined set of unitary logic gates acting on a specified initial state $|\psi_0\rangle$, after which a probabilistic measurement of the final quantum state is made. In a single qubit quantum computer every logic gate operation rotates the quantum state vector on the Bloch sphere to a new location such that during the computation the state vector traces out a specific path on the Bloch sphere. After that a measurement yields either spin-up or spin-down outcome and to find out the respective probabilities the computation must be repeated very many times.

Gate fidelity is a major issue of conventional quantum computation. That is, how accurately the action of the quantum gates can be realized by the quantum hardware as any such errors rapidly accumulate in the course of the computation. In a single qubit quantum computer every imperfect unitary gate operation will rotate the state vector slightly off the target, see Fig. 2(b), and these errors add up such that after all gates have been applied the final state vector may be far away from its correct location such that the probability of repeated measurements will ultimately converge to the completely random classical 50/50 measurement outcome. To certain extent the adverse effects of a noisy environment may be mitigated by implementing sophisticated error correcting protocols.

To go beyond single qubit quantum computation, generic many qubit states can be constructed by summing up tensor products of single qubit states. The many-qubit state (Hilbert) space whose dimension is $2^N = e^{N \ln(2)}$ grows exponentially rapidly with the number N of added qubits.³ An important resource in many-qubit quantum systems is entangled states, which cannot be expressed

¹Eq. (1) uses the non-unique yet conventional representation of the two qubit basis states.

²On each point on the Bloch sphere there is also an attached fiber that accounts for the quantum mechanically unmeasurable global phase degree of freedom ϕ that amounts to transformation $|\psi\rangle = e^{i\phi}|\phi_0\rangle$.

³Note that also the number of possible configurations of classical two-state on-off switches is equal to 2^N , however, where as after the computation (pre-determined flicking of the switches) there is one and only one observable outcome, the state of a quantum computer may be in a state where all of the 2^N states can have a non-zero probability of being measured.

as a tensor product of any two quantum states. In addition to these rudiments, a practically useful quantum computer will need to satisfy a range of additional criteria such as scalability to very large numbers of qubits (Divincenzo, 2000).

Fibonacci topological quantum computer

At the software level the operation of a topological quantum computer can be made to appear identical to that of a conventional quantum computer. The crucial difference occurs at the hardware level that enables the realization of fault tolerant qubits based on topology. Simplifying, the state vector rotations in a topological quantum computer can, in principle, be realized exactly even in the presence of noise sources that would cause the qubit rotations in a conventional quantum computer to be imprecise. In what follows, we will focus on the theoretical underpinnings of a braid group based topological quantum computer that uses Fibonacci anyons for its quantum logic operations.

Fusion rules

An anyon model that facilitates topological quantum computation is defined by its particle content and their fusion rules. The Fibonacci anyon model contains only one type of anyon, the non-abelian Fibonacci anyon τ in addition to the trivial vacuum state denoted by 1. The fusion rules of the Fibonacci anyon model are

$$\tau \otimes \tau = 1 \oplus \tau; \quad 1 \otimes \tau = \tau \otimes 1 = \tau; \quad \text{and} \quad 1 \otimes 1 = 1. \quad (4)$$

The first one of these is the most important one and states that when two Fibonacci anyons are brought together (fused) they may either annihilate each other yielding the vacuum 1 or combine to form a single Fibonacci anyon τ . This double valuedness of the fusion outcome can be used for defining a twolevel system—a topological qubit. It also means that the Fibonacci anyon may act as its own antiparticle. The latter two fusion rules correspond to “trivial” fusion outcomes.

When multiple Fibonacci anyons are fused sequentially, the possible fusion paths can be expressed using a fusion tree as illustrated in Fig. 3. The number of distinct fusion paths P_N as a function of the number N of anyons form a Fibonacci sequence, which gives the Fibonacci anyon its name. In the limit $N \rightarrow \infty$ the ratio P_N/P_{N-1} converges to the golden ratio $\phi = (1 + \sqrt{5})/2$, which is also the so-called quantum dimension of the Fibonacci anyon model.

Topological qubit

A well defined topological qubit may be conveniently constructed out of an array of four Fibonacci anyons ($\tau_1, \tau_2, \tau_3, \tau_4$), where the subscript denotes their spatial position in the array, by creating them pairwise from the vacuum, which guarantees that the initial state satisfies $\tau_1 \otimes \tau_2 = 1$ and $\tau_3 \otimes \tau_4 = 1$. The conservation of the topological charge $\tau_1 \otimes \tau_2 \otimes \tau_3 \otimes \tau_4 = 1 \otimes 1 = 1$ thus means that there remains two possible fusion paths for these four anyons

$$\tau \otimes \tau \otimes \tau \otimes \tau \rightarrow 1 \otimes \tau \otimes \tau \rightarrow \tau \otimes \tau \rightarrow 1 \cong |0\rangle$$

and

$$\tau \otimes \tau \otimes \tau \otimes \tau \rightarrow \tau \otimes \tau \otimes \tau \rightarrow \tau \otimes \tau \rightarrow 1 \cong |1\rangle$$

that can be used for the definition of a topological qubit. Measuring the state of the topological qubit may thus be determined solely by the fusion outcome of the first two anyons τ_1 and τ_2 . In words, if $\tau_1 \otimes \tau_2 = 1$ the qubit state is $|0\rangle$ and if $\tau_1 \otimes \tau_2 = \tau$ the qubit state is $|1\rangle$.

The state of the topological qubit can be changed by braiding the world lines of the anyons, which physically corresponds to moving the anyons around in the two-dimensional plane. Shuffling around the anyons in the two-dimensional physical space thus realizes unitary qubit rotations of the quantum mechanical state vector in the abstract state space, which is equivalent to the Bloch sphere in the case of a single qubit.

fusion tree	fusion paths	state
	$a \quad b \quad c$	
	$1 \rightarrow \tau \rightarrow 1$	$ 0\rangle$
	$1 \rightarrow \tau \rightarrow \tau$	not used
	$\tau \rightarrow 1 \rightarrow \tau$	not used
	$\tau \rightarrow \tau \rightarrow 1$	$ 1\rangle$
	$\tau \rightarrow \tau \rightarrow \tau$	not used

Fig. 3 Fusion of four Fibonacci anyons. Fusion of the four anyons sequentially from left to right leads to a fusion tree where the fusion outcome of the first two anyons is a , fusion of a with the third anyon yields b and fusion of b with the fourth anyon yields c . For four Fibonacci anyons there are five possible fusion paths that span the Hilbert space of possible state vectors. Topological charge conservation reduces the accessible state space from five to two, and these two fusion paths define a two level system (a topological qubit).

Braiding rules

When the anyons 1 and 2 are braided by moving them around each other counter-clockwise in the physical space to swap their positions, their world lines (string-like trajectories through space and time) become “knotted.” This operation is denoted by σ_1 . The inverse operation where the anyons are moved clockwise is denoted by σ_1^{-1} . If these two operations are performed one after another, the second operation undoes the first one such that $\sigma_1^{-1}\sigma_1 = \sigma_1\sigma_1^{-1} = 1$. Generally, braiding the anyons n and $n+1$ is denoted by braid operators σ_n and σ_n^{-1} . The braid operators acting on n strands (anyons) generate a braid group B_n . For a single Fibonacci anyon topological qubit it is sufficient to braid anyons 1, 2 and 3, while the fourth anyon does not need to participate in braiding so that its sole purpose is to ensure topological charge conservation of the four anyons. The qubit transformations may therefore be mapped onto the braid group B_3 . The two elementary braid operators of B_3 have explicit (truncated to a separable two-dimensional qubit subspace) matrix representations

$$\sigma_1 = \begin{pmatrix} e^{-i4\pi/5} & 0 \\ 0 & e^{i3\pi/5} \end{pmatrix} \quad (5)$$

and

$$\sigma_2 = \begin{pmatrix} \frac{e^{i4\pi/5}}{\phi} & \frac{e^{-i3\pi/5}}{\sqrt{\phi}} \\ \frac{e^{-i3\pi/5}}{\sqrt{\phi}} & -\frac{1}{\phi} \end{pmatrix} \quad (6)$$

and the operators σ_1^{-1} and σ_2^{-1} are the matrix inverses of σ_1 and σ_2 , respectively. These representations may be derived by solving the so-called pentagon and heptagon equations. An elementary topological quantum computation operation with Fibonacci anyons may thus be compactly expressed using standard notation

$$|\psi\rangle = \sigma_2|0\rangle = \begin{pmatrix} \frac{e^{i4\pi/5}}{\phi} & \frac{e^{-i3\pi/5}}{\sqrt{\phi}} \\ \frac{e^{-i3\pi/5}}{\sqrt{\phi}} & -\frac{1}{\phi} \end{pmatrix} \begin{pmatrix} 1 \\ 0 \end{pmatrix} = \alpha|0\rangle + \beta|1\rangle \quad (7)$$

and it physically corresponds to braiding the second and third anyon by exchanging their positions in real space, see Fig. 4, which in the abstract two-dimensional Hilbert space corresponds to creating a superposition state $|\psi\rangle$ in Eq. (7). By fusing the anyons after this braiding, the topological qubit would be found to be in the state $|0\rangle$ with a probability $P_0 = |\langle 0|\psi\rangle|^2 = |\alpha|^2 = \phi^{-2} \approx 0.4$ and in the state $|1\rangle$ with a probability $P_1 = 1 - P_0 = |\beta|^2 = \phi^{-1} \approx 0.6$.

Any single-qubit operation can be realized by concatenating L elementary braids to form a braid word $W_L = \sigma_{iL} \dots \sigma_{i2} \sigma_{i1}$ of length L and then acting with this braid word quantum gate on the initial state

$$|\psi\rangle = W_L|0\rangle. \quad (8)$$

Fig. 4 Topological quantum computation is realized by braiding Fibonacci anyons. Four Fibonacci anyons are first spawned pairwise from the vacuum to create a topological qubit. Identity operator (left diagram) leaves the qubit intact and a fusion at the end of the computation will yield a definite outcome with a probability 1. If the anyons two and three are braided (acting on the qubit with a σ_2 operator) the qubit is rotated into a superposition state and final fusion will then have two possible outcomes with respective probabilities of occurrence that add up to one.

Universality

An important enabling feature of the Fibonacci anyon model is that it is universal for the purposes of quantum computation. In simple terms this means that every quantum state that may be expressed in terms of the available qubits may also be transformed to any other one by braiding the anyons and without requiring any other operations. In the single-qubit case this means that it is possible to construct all possible quantum gates as products of the elementary braid matrices, such that it is possible to connect any two state vectors (points on the Bloch sphere) by braiding the anyons. This property holds true also in the case of many qubits that may be constructed by sequencing the available anyons into groups of four. For instance, using eight anyons one may construct two logical topological qubits each of which is comprised of four Fibonacci anyons. Two-qubit gates may then be realized by braiding anyons belonging to the different logical qubits.

Key issues

Presently, by far the most serious issue regarding Fibonacci anyons is their (non-)existence. Although it has been suggested that certain quasiparticles in exotic fractional quantum-Hall states could potentially serve for realizations of Fibonacci anyons, proving or refuting this is beyond current experimental capabilities. Even if this most severe limitation would be overcome in the future, several other technical obstacles remain that would need to be resolved.

While topological quantum computers are often stated to be immune to the kinds of environmental noise that affects the conventional quantum computers, they nevertheless are susceptible to error sources and challenges of their own, both at the software and the hardware levels.

Leakage error

Even in the single-qubit case where only the first three anyons are being braided, the full Hilbert space representable by the anyons is five dimensional. However, the braiding only acts on the two dimensional qubit subspace. For two or more qubits, this is no longer the case. For instance, the braid operators of a two-qubit system involving eight anyons act on a 13 dimensional Hilbert space, only 4 of which are used for defining the two-qubit states, such that operators $\sigma_1(1,2)$ and $\sigma_2(2,3)$ are intrinsic to the first qubit and the operators $\sigma_4(5,6)$ and $\sigma_5(6,7)$ are intrinsic to the second qubit, where the numbers in the parenthesis enumerate the anyons. However, the inter-qubit braid operator $\sigma_3(3,5)$ that braids the anyon τ_3 (in the first qubit) and the anyon τ_5 (in the second qubit) transfers population to some of the 9 so-called non-computational basis states. This is referred to as a leakage error as the probability leaks to quantum states not used for computational logic and this breaks the unitarity of the logic gates acting on the computational subspace. Although the amount of leakage can be mitigated by clever braiding protocols, this typically involves an additional computational overhead. This type of error could be completely avoided by making use of the full accessible Hilbert space and using multi-level qudits for computation instead of the more restricted two-level qubit basis and in this sense the leakage error is not a fundamental limitation of topological quantum computation.

Quantum compilation error

Another kind of error that affects topological quantum computers is the quantum compilation error. For instance, if one wishes to implement the Hadamard gate using a Fibonacci anyon based topological quantum computer, one must first compile the Hadamard gate. This means finding a braid word representation of H such that $W_L \approx H$. However, finding the optimal braid word of a fixed length L out of the exponentially, as a function of L , growing search space is a formidable task in its own right. Moreover, although universality of the Fibonacci anyon model guarantees that for every unitary U an arbitrarily good braidword approximation W_L may be obtained by increasing L , in practice for finite L , even the optimal W_L will only realize the target gate approximately. The compilation error thus has two parts, one due to the difficulty in finding the optimal braid word of given length L and another one due to the fact that even the optimal braid word will not in general be identical to the target gate.

As for the leakage error, the compilation error too could be mitigated by designing quantum computation algorithms that make direct use of the natural braid gates of the Fibonacci anyon model, rather than having to first compile a standard gate set from the elementary braids. The trade-off here is between computational efficiency and end-user convenience.

Hardware error sources

In addition to the error mitigation at the software level, topological quantum computers would also need to consider sources of errors originating from the hardware implementation of the anyons themselves such as the so-called quasiparticle poisoning. For instance, a pair of Fibonacci anyons could spontaneously form out of the vacuum and interfere with the braiding of the computational anyons. Material impurities or external causes could result in the appearance of patches of non-topological phases of matter, and in any physical realization there could exist so-far unidentified effects that could mimic braiding depending on how faithfully the physical system could be represented by the anyon model. These kinds of hardware level issues become important engineering considerations if non-abelian anyons will be proven to exist by experiments.

Conclusion

In summary, topological quantum computation is a form of quantum computation which is conducted using special kind of quantum hardware called non-abelian anyons. In a conventional quantum computer a rotation of a quantum state by a quantum gate is a continuous error prone operation in the sense that environmental noise may change the action of the quantum logic gate proportional to the strength of the noise leading to imprecise qubit rotations whose effects accumulate over the entire computation. By contrast, a topological quantum gate acts on the state vector either exactly or not at all, depending on the topology encoded in the world lines of the braided anyons. This special property could be harnessed to facilitate fault tolerant computations.

Here we have considered only one special kind of topological quantum computation model based on non-abelian Fibonacci anyons to illustrate some generic principles of topological quantum computation. Nevertheless, there exists a large variety of other types of anyon models. Perhaps the most promising one from the present day experimental physics perspective, the Ising anyon model, is based on Majorana fermion zero modes. Such non-abelian anyons are thought to be realizable by quantized vortices (Simula, 2019) in topological superfluids and at the end points of superconducting nano-wire structures.

Both the Fibonacci anyons and the Ising anyons belong to a broader (countably infinite) class of the so-called $SU(2)_k$ anyon models where the integer level $k = 3$ for the Fibonacci anyons and $k = 2$ for the Ising anyons. A major distinction between the $k = 2$ and $k = 3$ cases is that while the Fibonacci anyon model is universal for quantum computation, the Ising anyon model is not. This means that it is not possible to achieve full topological protection for the quantum computation in the $k = 2$ case, and that at least one quantum gate in the gate set of such a general purpose quantum computer must be implemented via non-topological means.

Another generic class of topological quantum computation models are the so called $D(H)$ quantum double models (de Wild Propitius and Bais, 1999). It has been suggested that such quantum double anyon models could potentially be realized by quantized vortices in spinor Bose–Einstein condensates (Mawson et al., 2019; G  netay Johansen and Simula, 2021). Such anyon models are based on representations of finite quantum groups and therefore, similarly to the Ising anyon models, they are not capable of universal quantum computation by braiding alone and need to be supplemented with non-topological gate operations.

At the time of writing, evolution of conventional quantum computers is still in its infancy and topological quantum computers do not yet exist. It will be exciting to see whether the future of scalable quantum computation will be based on topological or conventional qubits, or perhaps a combination of both?

Abstract

The fractional quantum Hall (FQH) effect refers to the strongly-correlated phenomena and the associated quantum phases of matter realized in a two-dimensional gas of electrons placed in a large perpendicular magnetic field. In such systems, topology and quantum mechanics conspire to give rise to exotic physics that manifests via robust quantization of the Hall resistance. In this chapter, we provide an overview of the experimental phenomenology of the FQH effect in GaAs-based semiconductor materials and present its theoretical interpretations in terms of trial wave functions, composite fermion quasiparticles, and enigmatic non-Abelian states. We also highlight some recent developments, including the Parton theory and the Dirac composite fermion field theory of FQH states, the role of anisotropy and geometrical degrees of freedom, and quantum entanglement in FQH fluids.

Key points

- describe the rich phenomenology exhibited by two-dimensional electrons hosted in a semiconductor system placed in a perpendicular magnetic field;
- overview of different theoretical approaches for describing fractional quantum Hall (FQH) phases of matter;
- introduce the concept of non-Abelian FQH states and their potential applications in fault-tolerant topological quantum computation;
- summarize recent developments in the field, including parton theory of the FQH effect, geometric properties of FQH states, entanglement-based and field-theoretic approaches to understanding FQH systems.

Notations and acronyms

$z = x - iy$	Complex number representation of the electron coordinates (x, y) in the 2D plane
ν	Filling factor
$\Phi_1 \equiv \prod_{i < j} (z_i - z_j)$	Laughlin-Jastrow factor
$\ell = \sqrt{\hbar/eB}$	Magnetic length
$\mathcal{P}_{\text{LLL}}$	Projection to the lowest Landau level
Φ_n	Wave function of n filled Landau levels
2DEG	Two-dimensional electron gas
B	Magnetic field strength
CF	Composite fermion
FQHE	Fractional quantum Hall effect
HLR	Halperin-Lee-Read
IQHE	Integer quantum Hall effect
LL	Landau level
LLL	Lowest Landau level
MR	Moore-Read
PH	Particle-hole
SLL	Second Landau level

Introduction

The fractional quantum Hall (FQH) effect occurs in a system of electrons confined to two spatial dimensions and a strong magnetic field perpendicular to the two-dimensional (2D) plane. In such systems, the kinetic energy is completely quenched by the magnetic field and Coulomb interaction exerts non-perturbative effects on the behavior of the electrons, typically without analogs in systems of weakly-interacting electrons encountered elsewhere in condensed matter physics. In this chapter, we do not aim to present a historical overview of the FQH effect, but rather highlight the key theoretical concepts for its understanding and to illustrate the connections between a variety of different approaches that have been deployed to tackle the problem. Perhaps most surprisingly, first-quantized wave functions have turned out to be highly valuable tools for understanding FQH phenomena, in contrast to the second-quantized field theories widely used in other areas of many-body physics. To emphasize this unique aspect of the FQH effect, our presentation will focus on introducing physics from the perspective of trial wave functions, motivated by experimental observations.

Before we dive into its fascinating experimental phenomenology, it is instructive to present a high-level description of the core of FQH physics. The following “Theory of Everything” Hamiltonian governing a FQH system should be familiar to most physicists:

$$H = \sum_j \frac{1}{2m_b} \left[p_j + \frac{e}{c} A \right]^2 + \sum_j U(r_j) + g\mu_B \mathbf{B} \cdot \mathbf{S} + \frac{e^2}{4\pi\epsilon} \sum_{j < k} \frac{1}{|\mathbf{r}_j - \mathbf{r}_k|}. \quad (1)$$

The first line contains the one-body terms in the problem: the kinetic energy in the presence of a constant external magnetic field $\mathbf{B} = \nabla \times \mathbf{A}$; the potential U incorporating the lattice, disorder and confinement effects; finally, the Zeeman energy. The second line is the Coulomb interaction energy between (non-relativistic) electrons.

As a first step, let us simplify the problem down to its bare essentials. While disorder, confinement and lattice effects can be occasionally very important, we will neglect them here and set $U = 0$. Most FQH experiments discussed below are performed using GaAs-AlGaAs heterostructures, in which electrons have a band mass of $m_b = 0.067m_e$ (where m_e is the electron mass in vacuum), dielectric constant of $\epsilon = 12.6\epsilon_0$, and Landé g factor $g = -0.44$. From this, we can estimate the energy required to flip a spin – the Zeeman splitting – to be $E_Z = g\mu_B B \approx 0.3B[\text{T}]\text{K}$, where the magnetic field $B[\text{T}]$ is in units of Tesla. With the exception of Section “Multicomponent fractional quantum Hall effect,” throughout this chapter, we will assume the electron spin is fully polarized due to a large magnetic field.

In order to diagonalize what’s left of the Hamiltonian, the usual strategy is to first diagonalize the one-body part of H which gives rise to discrete Landau levels (LLs) of a single electron in a magnetic field. The Landau solution yields two important scales in the problem: the magnetic length

$$\ell = \left(\frac{\hbar}{eB} \right)^{1/2} \approx \frac{25}{\sqrt{B[\text{T}]}} \text{nm}, \quad (2)$$

and the cyclotron energy splitting between LLs

$$\hbar\omega_c = \hbar \frac{eB}{m_b} \approx 20B[\text{T}]\text{K}. \quad (3)$$

On the other hand, the Coulomb energy scale is set by

$$V_C \equiv \frac{e^2}{4\pi\epsilon\ell} \approx 50\sqrt{B[\text{T}]}K. \quad (4)$$

The values on the rightmost side of Eqs. (3) and (4) are quoted for GaAs-based samples.

For the sake of convenience, throughout we shall use natural units where $\ell = 1$ and $e^2/(4\pi\epsilon\ell) = 1$.

To render the many-body problem as tractable as possible, one often makes a further approximation by choosing $V_C \ll \hbar\omega_c$. In this limit, the Coulomb interaction is too weak to scatter particles across different LLs, i.e., entire dynamics is contained within a single LL and there is no “LL mixing.” This assumption is not always warranted and its validity should be tested either numerically or experimentally. Nevertheless, under this approximation, the FQH Hamiltonian takes a remarkably simple form

$$H = \mathcal{P} \left(\frac{e^2}{4\pi\epsilon} \sum_{j < k} \frac{1}{|\mathbf{r}_j - \mathbf{r}_k|} \right) \mathcal{P}, \quad (5)$$

i.e., the Hamiltonian is just the Coulomb interaction which must be diagonalized with the restriction of remaining in a single LL. The latter restriction is formally implemented by the global operator $\mathcal{P}$ which projects out all states that have a component outside the given LL. For most of our discussion below, the LL in question will be the lowest LL (LLL), although we will also mention the second LL (SLL) and higher LLs.

The model in Eq. (5) embodies the theoretical essence of the FQH effect: it is believed to capture universal physical properties of broad classes of correlated phases emerging in the regime of the FQH effect. However, despite its seemingly simple form, it is impossible to analytically diagonalize the Hamiltonian of Eq. (5). The difficulty stems from $\mathcal{P}$ being a global operator defined on a many-electron Hilbert space whose dimension grows exponentially with the number of electrons. Specifically, two main challenges are: (i) Eq. (5), has no parameters whatsoever, including no-small parameters that one might use to attempt a perturbative approach; (ii) If the Coulomb interaction is turned off, one ends up with an exponentially large degeneracy of any LL, again precluding an easy solution.

Broadly speaking, this chapter will focus on the following questions: (i) what are the possible phases of matter that arise from Eq. (5) as one varies the electron density (or, alternatively, the magnetic field)? (ii) what are the universal properties of such phases in the long-wavelength limit, e.g., the types of order and excitations that govern the low-energy physics? (iii) what are the fundamental principles that allow us to understand and microscopically model such phases?

Phenomenology of the FQH effect

In a typical FQH experiment, one measures the Hall resistance, extracted from the voltage drop perpendicular to the current flowing through a two-dimensional electron gas (2DEG) placed in a perpendicular magnetic field. The 2DEG should have sufficiently low concentration of impurities and high mobility of the electrons. The fabrication of such samples has required major technological advances that we will not touch upon. As found by Tsui et al. (1982), upon sweeping the magnetic field, the Hall resistance of such a 2DEG exhibits quantization at

$$R_{xy} = \frac{h}{\nu e^2}, \quad (6)$$

where ν was originally found to take the value $1/3$. Subsequently, quantization was observed at other rational values of ν such as $2/3$, $2/5$, $3/7$, etc. On the other hand, ν is related to the electron density ρ and is known as the *filling factor* or *filling fraction*,

$$\nu = \frac{\rho h}{eB}. \quad (7)$$

In an earlier work by Klitzing et al. (1980), similar resistance quantization had been observed for integral values of ν , i.e., in the regime of integer quantum Hall (IQH) effect. In both cases, the resistance was found to be quantized not only at the special value of ν but also in some neighborhood around the special value, which manifests as a resistance plateau in the experimental trace, as illustrated in the experimental data shown in Fig. 1A. Furthermore, when R_{xy} is pinned to a plateau, the longitudinal resistance (i.e., the one measured along the direction of the current) exhibits an Arrhenius behavior $R_{xx} \propto \exp(-\Delta/(2k_B T))$, where the energy scale Δ is interpreted as a gap to excitations. R_{xx} vanishes in the limit $T \rightarrow 0$, indicating dissipationless transport. A deep minimum in R_{xx} is often seen as a precursor of a developing FQH state, however, the definitive observation of a FQH state requires a quantized plateau in R_{xy} .

In both IQH and FQH cases, the R_{xy} quantization is remarkably accurate to about one part in a billion. This is a manifestation of quantum-mechanical coherence across a semiconductor material on mesoscopic length scales. Moreover, as seen from the appearance of the Planck constant, the quantization is not described by classical electrodynamics. The latter also predicts that the resistance should vary linearly with the magnetic field. One hint to a topological origin of the phenomenon is that the resistance is quantized, not the resistivity (they both have the same units in two dimensions). Moreover, the Hall quantization was found to be universal: it is independent of the sample type, geometry, and various materials parameters, such as the band mass of the electron or the dielectric constant of the background semiconductor, and is robust to sufficiently weak disorder.

Fig. 1 Experimental measurements of the Hall resistance R_{xy} and the longitudinal resistance R_{xx} as a function of the magnetic field B applied perpendicularly to a 2DEG. (A) Resistance traces in the lowest Landau level from Ref. Pan et al. (2003). Prominent gapped states are shaded in yellow. Other weaker states (without fully developed minimum in R_{xx}) are also indicated. The composite Fermi liquid is shaded purple. (B) In the second Landau level, in addition to gapped states at odd-denominator filling factors, there are also even-denominator states at $\nu = 2 + 1/2$ and $\nu = 2 + 3/8$. Reentrant integer quantum Hall states are shaded in green. (C) In higher Landau levels, the FQH plateaus are replaced by states with strongly anisotropic transport, as revealed by the large difference between R_{xx} and R_{yy} . Examples are shaded in red and identified with stripe phases. Reentrant integer quantum Hall states are shaded in green. Incompressible fluids

Performing the transport measurements described above, one obtains remarkable traces of R_{xy} and R_{xx} as a function of the magnetic field B , as we illustrate in Fig. 1 using current state-of-the-art experimental data. At sufficiently low temperatures (typically, in mK range) and very high magnetic fields, the trace is dominated by FQH states which display a quantized plateau in R_{xy} and vanishing R_{xx} . These are signatures of incompressible quantum fluids, which arise from strong Coulomb repulsion between the electrons residing in the partially-filled LLL, as the kinetic energy of the electrons is quenched. FQH fluids are unconventional in that they represent topological phases of matter. While a detailed theory of such topological quantum fluids will be presented in subsequent sections, here we briefly summarize some of their defining properties – see Fig. 2:

- FQH phases are quantum liquids that do not exhibit long-range order for any local order parameter. Thus, FQH phases cannot be described by a Landau-Ginzburg type theory based on spontaneous symmetry breaking [Prange and Girvin \(1987\)](#). For example, the (LL-projected) structure factor of a FQH state, shown in inset of Fig. 2B, takes the form characteristic of a liquid phase, indicating that the FQH state is uniform in the bulk and distinct from, say, a Wigner crystal.
- The bulk of a FQH fluid exhibits an energy gap Δ , i.e., there is a discontinuity in the chemical potential as one sweeps the magnetic field. Furthermore, there is also a gap for charge-neutral excitations at the fixed magnetic field, as seen in Fig. 2B. Near the system's boundary, however, there are *gapless* charged excitations which propagate chirally, in the direction determined by the external magnetic field, see Fig. 2A. In the semiclassical picture, these excitations can be visualized as “skipping orbits” [Halperin \(1982\)](#), which can also go around weak impurity potentials, avoiding dissipation.

Fig. 2 Incompressible fluids and topological order. (A) Transport experiment probing a FQH state. Robust quantization of the Hall resistance is associated with a current-carrying edge state (yellow), which is insensitive to a low concentration of impurities (depicted in pink). In a semiclassical picture, the edge state forms a narrow one-dimensional channel that propagates ballistically in one direction. (B) On a torus, the $\nu = 1/3$ FQH ground state has a three-fold topological degeneracy and carries zero momentum $\mathbf{K} = 0$, while the rest of the energy spectrum is separated by a gap. Low energy charge-neutral excitations form a collective mode. Data is obtained using DiagHam open source package [DiagHam](#) for exact diagonalization of the Coulomb interaction projected to the lowest LL for $N \leq 12$ electrons. The same plot includes data for both square and hexagonal unit cells, illustrating the robustness of the low-energy physics to geometric details. Inset shows the projected guiding-center structure factor $S_0(\mathbf{k})$, which reveals a liquid ground state. (C) Elementary charged excitations of a FQH fluid behave as anyons: by taking two anyons around each other, the resulting wave function Ψ_{final} is not simply equal to $\pm\Psi_{\text{initial}}$, as it would be for bosons or fermions.

- The ‘topological’ nature of the FQH fluid is manifested in its sensitivity to the topology of the manifold it lives in. For example, in the infinite plane or when wrapped around a sphere, the fluid has a unique ground state, but when it is placed on a torus or any higher genus surface, the ground state develops a degeneracy [Wen and Niu \(1990\)](#). At filling factor $\nu = p/q$, with p, q coprime positive integers, the ground state degeneracy is at least q [Haldane \(1985\)](#). For example, in the $\nu = 1/3$ state shown in [Fig. 2B](#), the ground state is three-fold degenerate on the torus.
- By threading magnetic flux or, equivalently, by twisting the torus boundary conditions, the degenerate ground states can mix with one another but remain separated from other excited states by the energy gap Δ . The total Hall conductance carried by the ground state multiplet is proportional to the topological invariant called the Chern number C [Thouless et al. \(1982\)](#). This gives the Hall conductance for each member of the multiplet $\sigma_{xy} = \nu \frac{e^2}{h}$. The topological nature of the Hall conductance explains its robustness at sufficiently low temperatures $k_B T \ll \Delta$.
- Thermal Hall conductance of FQH fluids is given by [Kane and Fisher \(1997\)](#)

$$\kappa_{xy} = c_- [\pi^2 k_B^2 / (3h)] T. \quad (8)$$

where the universal coefficient c_- is known as the chiral central charge. This expression holds at temperatures much smaller than the gap and under the assumption that edge modes are fully equilibrated.

- The excitations of incompressible FQH fluids are *anyons* [Leinaas and Myrheim \(1977\)](#) and [Wilczek \(1982\)](#): an exotic type of particle which carry a fraction of the electron charge and also have “fractional” exchange statistics [Arovas et al. \(1984\)](#). In particular, for states such as $\nu = 1/3$ depicted in [Fig. 2C](#), the adiabatic exchange of the coordinates of two anyons results in a complex phase, $\Psi_{\text{final}}(z_2, z_1) = e^{i\theta} \Psi_{\text{initial}}(z_1, z_2)$ with $\theta = 2\pi/3$. Bosons and fermions are special cases with $\theta = 0$ and $\theta = \pi$, respectively, while Abelian anyons correspond to other real values of θ . Anyons with richer exchange statistics are also possible and will be discussed in Section “Non-Abelian states”. We note that recent experiments have observed statistical properties of the simplest types of Abelian anyons in the $\nu = 1/3$ state using mesoscopic interferometry [Nakamura et al. \(2020\)](#) as well as anyon colliders [Bartolomei et al. \(2020\)](#).
- FQH fluids can be described by an emergent Chern-Simons gauge field $\mathbf{a}$, which attaches magnetic fluxes to particles [Zhang et al. \(1989\)](#). This enables the transmutation of statistics and the existence of anyon excitations. The Chern-Simons field contributes a topological term to the effective action of FQH fluids,

$$\mathcal{L}_{\text{CS}} = \frac{1}{4\pi\nu} \varepsilon^{\mu\nu\lambda} a_\mu \partial_\nu a_\lambda, \quad (9)$$

where $\varepsilon^{\mu\nu\lambda}$ is the Levi-Civita tensor and we assumed the simplest FQH state is at filling $\nu = 1/q$, with Einstein summation convention implied. Thus, the effective low-energy theory of FQH fluids is a variant of topological quantum field theory (see Section “Effective field theory” for further discussion).

The properties summarized in this section are believed to be shared by all incompressible FQH states, which are primarily realized in the LLL and SLL, recall [Fig. 1A](#) and [B](#). However, as we explain below, the microscopic mechanisms giving rise to these topological fluids can be very different. In particular, the FQH states in the LLL are markedly different from those in the SLL. In contrast to the majority of gapped FQH liquids presented in [Fig. 1A](#), we note that there also exists a *gapless* liquid state which is similar to the Fermi liquid state in an ordinary 2DEG in zero magnetic field. This state occurs at $\nu = 1/2$ where one observes a smooth dependence of both the longitudinal and Hall resistances in [Fig. 1A](#). Nevertheless, this Fermi-liquid-like state has many exotic properties of its own and it will be discussed separately in Section “Gapless composite fermion Fermi liquid in the half-filled Landau level”.

We note here that FQH states extending on either side of $\nu = 1/2$ are related by an operation that maps electrons to holes and vice versa, i.e., it relates states at ν with $1 - \nu$. This particle-hole (PH) symmetry is exact in the limit $B \rightarrow \infty$. In this limit, any two-body interaction, like the Coulomb one, results in eigenstates that are perfectly PH symmetric. We will return to the consequences of PH symmetry in Sections “Anti-Pfaffian” and “Effective field theory”.

Broken symmetry phases

In addition to incompressible liquids, other types of correlated phases of matter can occur in partially filled LLs, primarily in the regime of low filling factors or in higher LLs, see [Fig. 1B](#) and [C](#) ([Ro et al., 2019](#)). While interactions still underpin the formation of such phases, these phases spontaneously break the translation symmetry of the 2D plane by forming crystals or stripe patterns ([Fig. 3](#)). Such phases are typically weakly-correlated and they have been successfully understood using the more traditional methods, such as Hartree-Fock theory.

Wigner crystals in the lowest Landau level

“Classical” electrons at sufficiently low densities in 2D form a triangular Wigner crystal (WC) (see [Fig. 3](#)) to minimize the Coulomb repulsion between them. Strong magnetic field quenches the kinetic energy of the electrons, leaving only interactions to decide the fate of the system. This setting was believed to be ideal to stabilize the WC phase and provided one of the motivations for the Tsui-Stormer-Gossard experiment [Tsui et al. \(1982\)](#).

As it turned out, the FQH liquid has lower energy than WC at high filling factors [Yoshioka et al. \(1983\)](#). However, at very low filling factors, when the density of electrons is sufficiently small, a WC is expected to be stabilized. Recent studies suggest that the

Fig. 3 Some examples of symmetry-broken phases realized in a two-dimensional electron gas placed in a strong perpendicular magnetic field.

FQH fluid can prevail over the WC at filling factors as low as $\nu = 1/7$ Pan et al. (2002), Chung et al. (2022). Furthermore, the WC that is stabilized at $\nu < 1/7$ is not that of electrons, but of electron-vortex composites called composite fermions (CFs) Archer et al. (2013) and Zuo et al. (2020), that we will introduce in Section “Composite fermions”.

While direct signatures of the Wigner solid phase have remained elusive, experiments have observed a number of indirect signatures. The presence of a WC has been probed by studying the commensurability oscillations of CFs in a nearby layer Deng et al. (2016). Collective oscillations of the crystalline domains of the WC resulting from disorder give rise to “pinning resonances” in the frequency-dependent conductivity which have been detected experimentally (Williams et al., 1991; Zhu et al., 2010). The melting behavior of the magnetic-field-induced WC suggests that it harbors quantum correlations and is markedly different from the classical WC at zero-field Ma et al. (2020).

Stripes, nematics and bubble crystals in higher LLs

In higher LLs, interactions can also engender various phases that spontaneously break certain symmetries while exhibiting integral quantization of the Hall resistance, as seen in Fig. 1B and C. In the vicinity of integral fillings, if disorder is sufficiently weak, the additional electrons or holes are expected to form a WC. Using Hartree-Fock theory, Koulakov et al. (1996) and Fogler et al. (1996) predicted that the extra electrons or holes in a high LL have a tendency to form a WC, a “bubble” phase – a WC of bubbles of electrons, where each bubble hosts multiple electrons, or stripes of alternating fillings, depending on the filling factor (see Fig. 3). For example, when a high LL is nearly half full (i.e., the filling factor is $\nu = n + 1/2$ with n being a sufficiently large integer), strong transport anisotropy is observed, as shown in Fig. 1C, consistent with the formation of stripes (see Fig. 3) (Du et al., 1999; Lilly et al., 1999). The direction of the anisotropy aligns with one of the crystal axes, due to the explicit symmetry breaking via the host lattice. Moreover, the anisotropy can flip by 90° as a function of the in-plane magnetic field Lilly et al. (1999) or the density Zhu et al. (2002). Many re-entrant transitions are seen in higher LLs (Eisenstein et al., 2002; Xia et al., 2004), indicating competition between numerous approximately degenerate ground states Shibata and Yoshioka (2001) with a common feature of integral Hall resistance quantization.

Laughlin states

Laughlin’s wave function

Soon after the experimental observation of the FQH plateau at $\nu = 1/3$, Laughlin constructed a novel ansatz to describe the electronic ground state at this filling Laughlin (1983). Laughlin’s wave function is given by

$$\Psi_{\nu=1/(2p+1)}^{\text{Laughlin}} = \prod_{i < j} (z_i - z_j)^{2p+1} \exp \left[-\sum_k \frac{|z_k|^2}{4\ell^2} \right] \equiv \Phi_1^{2p+1}, \quad (10)$$

where $z_k = x_k - iy_k$ parametrizes the 2D coordinate of the k^{th} electron as a complex number, and p is a positive integer ($p = 1$ for $\nu = 1/3$). The $\nu = 1$ IQH wave function, $\Phi_1 = \prod_{i < j} (z_i - z_j)$, is referred to as the Laughlin-Jastrow factor. To simplify the notation, below we shall often drop the ubiquitous Gaussian factor and the subscript “ ν ” from the wave functions.

The high power of the Jastrow factor in the Laughlin wave function builds additional correlations in the many-body state (beyond those mandated by the Pauli principle) which keeps the electrons away from each other and thus minimizes their Coulomb repulsion. Because of this, one may expect the wave function in Eq. (10) to provide a good variational description of the exact ground state of the Hamiltonian in Eq. (5). Quite remarkably, it turned out that the overlap between the Laughlin wave function and the exact ground state of Eq. (5) for as many as $N = 15$ electrons is consistently above 98%, despite an exponential increase in the size of the Hilbert space with N and the lack of any variational parameters in Eq. (10). This suggests that the Laughlin wave function captures all the essential correlations of the $\nu = 1/3$ ground state even in the thermodynamic limit. Indeed, due to the “nice” form of the Laughlin wave function, many of its properties such as energy, density, pair-correlation function etc. have been studied in large systems using the Monte Carlo method Morf and Halperin (1986). The (projected) structure factor of the $\nu = 1/3$ state, shown in inset of Fig. 2B, confirms that the state describes an incompressible liquid.

Laughlin’s theory furthermore predicts that the FQH effect can also occur at $\nu = 1/5$ and a quantized Hall plateau at this filling was observed in experiments. Subsequent numerical simulations have shown that the Laughlin wave functions have high overlaps with the exact LLL Coulomb ground state for small systems at $\nu = 1/3, 1/5$ and $1/7$ Fano et al. (1986), d’Ambrumenil and Reynolds

(1988). For $\nu < 1/7$, a Laughlin liquid is expected to give way to a crystalline state [Lam and Girvin \(1984\)](#). By particle-hole conjugation in the LLL, Laughlin's theory also explains the plateaux observed at fractions $\nu = 1 - 1/(2p + 1)$ which can be understood as a $1/(2p + 1)$ Laughlin state of "holes."

Charged excitations

Laughlin also constructed wave functions for the charged excitations in this system. Laughlin's wave function for the positively charged excitation, referred to as a *quasihole* (qh), located at a position η , is given by:

$$\Psi_{1/(2p+1)}^{\text{Laughlin,qh}} = \prod_i (z_i - \eta) \Psi_{1/(2p+1)}^{\text{Laughlin}} \quad (11)$$

while that of the negatively charged *quasiparticle* (qp) is:

$$\Psi_{1/(2p+1)}^{\text{Laughlin,qp}} = \prod_i (2\partial_{z_i} - \bar{\eta}) \Psi_{1/(2p+1)}^{\text{Laughlin}} \quad (12)$$

In Eq. (12) the derivatives only act on the polynomial part of the wave function and not on the Gaussian factor. To motivate these wave functions, consider the situation where $\eta = 0$. The polynomial factor $\prod_i z_i$ pushes electrons away from the origin (the wave function of Eq. (11) vanishes at η) thereby depleting the electron density at the origin resulting in the creation of a positively charged quasihole. The derivatives, on the other hand, pull electrons in towards the origin which leads to a build-up of an excess charge at the origin resulting in the creation of a negatively charged quasiparticle.

The probability density corresponding to Laughlin's ground state and quasihole wave functions can be interpreted as the partition function of a one-component classical plasma in 2D [Laughlin \(1987\)](#). Using this plasma analogy, Laughlin showed that the quasihole excitation carries a fractional charge of $e/(2p + 1)$ (we denote the electronic charge by $-e$). Via PH conjugation, one can readily see that the quasiparticle excitation also carries a fractional charge of value $(-e)/(2p + 1)$. Shot-noise experiments have verified the presence of $-e/3$ charged quasiparticles in the $\nu = 1/3$ state ([Saminadayar et al., 1997](#); [Dolev et al., 2008](#)). Moreover, recent experiments [Bartolomei et al. \(2020\)](#) and [Nakamura et al. \(2020\)](#) have confirmed that the quasihole and quasiparticle excitations of the Laughlin state are Abelian anyons with a statistical phase $\theta = 2\pi/3$.

Magnetoroton excitation

Along with charged excitations, any FQH system, including the Laughlin states, also hosts "neutral" excitations which can be viewed as arising from a combination of an equal number of quasiparticles and quasiholes. Girvin, MacDonald, and Platzman (GMP) [Girvin et al. \(1985\)](#) proposed a general ansatz for the lowest-lying neutral excitation as a density wave riding on the ground state. The GMP wave function is written as $\Psi_{\nu,k}^{\text{GMP}} = \bar{\rho}_k \Psi_\nu$, where $\bar{\rho}_k$ is the LLL projected density operator and Ψ_ν is the ground state wave function at filling ν . The GMP excitation is termed a *magnetoroton* since its dispersion has a characteristic minimum at a finite wavenumber reminiscent of the roton minimum in the excitation spectrum of liquid Helium. The GMP ansatz gives a reasonable account of the exact low-lying neutral excitation at wavenumbers near and below the roton minimum, $kl \lesssim 1$ [He et al. \(1994\)](#). Resonant inelastic light-scattering experiments have mapped out the magnetoroton branch of excitations at $\nu = 1/3$ [Pinczuk et al. \(1993\)](#).

Edge excitations

As we sketched in [Fig. 2A](#), due to the insulating bulk, the conduction in FQH states occurs in the vicinity of the system's boundary via chiral edge channels. In the FQH effect, electron correlations are strong and one must model the edge channels using the Luttinger liquid description [Wen \(1990\)](#). Theoretical description of FQH edge states is provided by bosonization, which conveniently expresses the electronic degrees of freedom in terms of bosons. Due to chirality, backscattering in wide samples is minimized and the edge channels are found to propagate ballistically across long distances, with the dispersion $\epsilon_k = vk$, where v is the edge speed and k is the momentum along the edge.

In real samples, however, the edge may undergo a phenomenon of "reconstruction" [Chklovskii et al. \(1992\)](#), [Chamon and Wen \(1994\)](#) where instead of a single channel, the edge consists of compressible and incompressible stripes that form multiple parallel conducting channels, possibly counterpropagating. Unlike the insulating bulk, the physics of the edge is thus far more prone to non-universal effects due to the long-range tail of the Coulomb interaction and details of the confining potential near the boundary of the system.

The edge spectral function can be measured by tunneling an electron laterally into the edge. Wen's theory [Wen \(1990\)](#) predicts a nonlinear current-voltage, $I \propto V^m$, relation at zero temperature, with the edge exponent taking the quantized value $m = 2p + 1$ for the $\nu = 1/(2p + 1)$ Laughlin states. Thus, the quantized edge exponent distinguishes a FQH edge from an ordinary Luttinger liquid, whose edge exponent varies continuously with the strength of the interaction. The edge exponent was measured in experiments by [Chang et al. \(1996\)](#) who found its value to be reasonably close to 3 in the $\nu = 1/3$ state. However, various non-universal effects have also been observed in these experiments [Chang \(2003\)](#). This makes the study of FQH edges challenging even in the simplest fractions such as $\nu = 1/3$.

Parent Hamiltonian and Haldane pseudopotentials

An important step in validation of Laughlin's theory was Haldane's identification of a parent Hamiltonian for the state in Eq. (10) Haldane (1983). Any homogeneous and isotropic pairwise interaction potential $V(|z_i - z_j|)$, with the particles restricted to a single LL, can be written as Duncan Haldane (1990)

$$H_{\text{int}} = \sum_{i < j} V(|z_i - z_j|) = \sum_m \sum_{i < j} V_m \hat{P}_{ij}^m, \quad (13)$$

where $\hat{P}_{ij}^m$ projects onto a state in which particles i and j have relative angular momentum m . In the LLL, $\hat{P}_{ij}^m$ projects on the relative state $\psi_{\text{rel}} \sim (z_i - z_j)^m$ of any pair of particles. The numbers V_m are called the Haldane pseudopotentials and they represent an energy penalty for two particles to form a state with relative angular momentum m . For spinless electrons, only odd values of m can appear as ψ_{rel} must be fully antisymmetric in electrons' coordinates.

The parent Hamiltonian of the $\nu = 1/3$ Laughlin state is obtained by setting $V_1 > 0$ and all other $V_{m \geq 3} = 0$. This interaction assigns positive energy to any wave function that vanishes as $\psi_{\text{rel}} \sim (z_i - z_j)$, but it allows pairs of particles to form the state $\psi_{\text{rel}} \sim (z_i - z_j)^3$ for free. The latter is just the $p = 1$ Laughlin state in Eq. (10), which emerges as the unique and densest state with exactly zero energy for the V_1 pseudopotential interaction. The quasi-hole excitations of the Laughlin state, Eq. (11), similarly appear as exact zero-energy states of the same Hamiltonian. Numerics on finite systems show that any other state in the spectrum is separated by a gap on the order $\Delta \propto V_1$ but the persistence of this spectral gap in the thermodynamic limit has not been rigorously proven.

Haldane pseudopotentials greatly facilitate numerical modelling of FQH systems. For example, open-source libraries for exact diagonalization of FQH systems such as DiagHam DiagHam take full advantage of the pseudopotential formalism. On the analytical side, an arbitrary combination of pseudopotentials can be conveniently converted to a real space potential Trugman and Kivelson (1985), which enables systematic studies of parent Hamiltonian of more complex FQH states Simon et al. (2007a).

Hierarchy and composite fermions

Following the discovery of the $\nu = 1/3$ state, a zoo of more than a hundred FQH plateaux have been observed, many of which do not fit Laughlin's theory (see Fig. 1). These fractions predominantly belong to the sequence $\nu = n/(2pn \pm 1)$ [and their hole-conjugates at $1 - n/(2pn \pm 1)$], where n and p are positive integers (see Fig. 1). Consequently, new theoretical approaches had to be developed to describe such states. In this chapter we focus on two leading paradigms for understanding the various fractions observed the lowest LL: the Haldane-Halperin hierarchy and Jain's composite fermion theory.

Haldane-Halperin hierarchy

Haldane (1983) and Halperin (1984) proposed a hierarchical construction to obtain FQH states at arbitrary odd-denominator fractions. In the hierarchical construction, one starts with a nearby parent Laughlin state and views the filling factor difference from it as stemming from the presence of additional Laughlin quasiparticles/quasiholes. Assuming that interaction between the additional Laughlin quasiparticles/quasiholes is sufficiently strongly repulsive at short distances and weak in comparison to the parent Laughlin state, one condenses these excitations into Laughlin-like "daughter" FQH states. Iterating such a construction, one can produce candidate FQH states at all odd-denominator fractions – see Fig. 4 for the fractions originating from the $\nu = 1/3$ Laughlin state in the first three generations of a hierarchy.

A trial wave function for the first daughter state at filling factor $\nu = 1/(2p + 1 - q^{-1})$, where q is a positive even integer, with N electrons and N/q Laughlin quasiparticles is constructed as follows:

Fig. 4 Daughter fractions obtained from the Haldane-Halperin hierarchy originating from the parent Laughlin state at $\nu = 1/3$. Experimentally observed fractions in the lowest Landau level are circumscribed.

$$\int \left[\prod_{k=1}^{N/q} d^2 \eta_k \right] [\Phi_1^*(\{\bar{\eta}_k\})]^q \Psi_{1/(2p+1)}^{\text{Laughlin, qps}}(\{z\}; \{\eta_k\}), \quad (14)$$

where Φ_1 is the usual Laughlin-Jastrow factor and the term $\Psi_{1/(2p+1)}^{\text{Laughlin, qps}}$ is the Laughlin quasiparticle state of Eq. (12) generalized to multiple quasiparticles located at positions η_k . Analogous wave functions for the first daughter state at $\nu = 1/(2p + 1 + q^{-1})$ can be constructed from Laughlin's quasihole wave function of Eq. (11). The same idea can be used to construct wave functions for daughter states further down in the hierarchy.

For small systems at $\nu = 2/5$ and $3/7$, the hierarchical wave functions have been constructed numerically and these have high overlaps with the exact LLL Coulomb ground states Greiter (1994). Studies of larger systems and other filling factors are required to substantively test these wave functions. The order of fractions and their stability predicted by the hierarchy theory is not entirely consistent with experiments. For example, the $3/7$ and $5/13$ states appear at the same level in the hierarchy (see Fig. 4) but the FQH effect at $3/7$ is much stronger than that at $5/13$ as is evidenced from their gaps [see Fig. 1A]. Nonetheless, universal aspects, such as the charge and braiding statistics of the quasiparticles, predicted by the Haldane-Halperin construction are consistent with experiments.

Composite fermions

Jain's theory Jain (1989a) provides a conceptually different microscopic explanation of the $\nu = n/(2pn \pm 1)$ FQH states as IQH states of certain emergent topological particles called *composite fermions* (CFs). A composite fermion is a bound state of an electron and an even number ($2p$) of vortices. Due to the vortex-binding, the CFs see a reduced magnetic field $B^* = B - 2p\phi_0$ compared to the external magnetic field B seen by the electrons [superscript $*$ is used to denote CF quantities]. The $+$ (parallel) and $-$ (anti-parallel) signs in $\nu = n/(2pn \pm 1)$ indicate the direction of the residual magnetic field seen by the CFs with respect to the external magnetic field. In the zeroth-order approximation, the CFs are assumed to be non-interacting, and just like free electrons in a magnetic field, CFs form their own Landau-like levels, called *Lambda levels* (Λ Ls). When an integer number $\nu^* = n$ of these Λ Ls are fully filled, we get an FQH effect of electrons at $\nu = n/(2pn \pm 1)$. The existence of Λ Ls has been established in experiment Kang et al. (1993). Recently, in an ultra-high mobility sample, FQH states all the way up to $n = 16$ in the $n/(2n \pm 1)$ Jain sequence have been observed Chung et al. (2021).

The mapping to an IQH effect leads to the Jain wave function for the FQH ground state at $\nu = n/(2pn \pm 1)$ Jain (1989a)

$$\Psi_{n/(2pn \pm 1)}^{\text{Jain}} = \mathcal{P}_{\text{LLL}} \Phi_1^{2p} \Phi_{\pm n}. \quad (15)$$

Here Φ_n is the Slater determinant state of n filled LLs of electrons, while the Jastrow factor Φ_1^{2p} attaches $2p$ vortices to each of the electrons to convert them into CFs, see Fig. 5 for a schematic illustration. For $n = 1$ (with the $+$ sign) the Jain wave function is identical to the Laughlin wave function of Eq. (10). For $n > 1$, the Jain wave function needs to be explicitly projected to the LLL, as denoted by $\mathcal{P}_{\text{LLL}}$.

Beyond ground state properties, the IQH mapping readily allows the construction of wave functions for the excitations as well, see Fig. 5. The positively charged quasihole called a CF hole is obtained by removing a CF from the topmost filled Λ L. The negatively charged quasiparticle, referred to as a CF particle, is obtained by adding a CF in the bottommost empty Λ L. The lowest-lying neutral excitation, called the CF-exciton, is obtained by combining a single CF particle and a CF hole. The excitations obtained using CF theory generally exceed the accuracy of other approaches, e.g., the Laughlin and GMP ansatz discussed in Section "Laughlin states," in describing the exact LLL Coulomb excited states.

We note here that although the Haldane-Halperin hierarchical states are topologically equivalent to CF states Read (1990), Wen (1995), the two theories propose different microscopic mechanisms for the origin of FQH effect Jain (2014). Unlike the hierarchy wave functions, the CF wave functions in Eq. (15) have proven amenable to large-scale numerical simulations Jain and Kamilla (1998). These studies have demonstrated that the CF theory provides a highly-accurate description of the majority of FQH states observed in the LLL. For example, neutral excitation spectrum observed using surface acoustic waves Kukushkin et al. (2009) is in good agreement with CF theory Scarola et al. (2000). Nevertheless, some quantitative discrepancy between the experimentally measured (Boebinger et al., 1985; Willett et al., 1988; Du et al., 1993; Pan et al., 2020; Villegas Rosales et al., 2021) and theoretically

Fig. 5 Schematic representation of CF ground state, elementary charged and neutral excitations at $\nu = 3/7$.

predicted (Zhang and Das Sarma, 1986; Ortalan et al., 1997; Morf et al., 2002) charge gaps persists to this day. This likely arises from neglecting the effects of the disorder, interface roughening, and screening by gates in theoretical studies. Furthermore, theoretical calculations use simplified models to incorporate the effects of LL mixing and finite-width. More realistic calculations are needed to quantitatively explain the gaps obtained in experimental studies. Finally, certain delicate states, like those observed at $\nu = 4/11$ and $5/13$ (Samkharadze et al., 2015; Pan et al., 2015), Fig. 1A, and the states seen in the SLL, Fig. 1B, lie beyond the paradigm of *weakly-interacting* CFs presented in this section. To understand such states, one needs other approaches, as discussed in subsequent sections below.

Half-filled Landau level

The simplest fraction – half-filling of a LL – has remained in the focus of research since the early days of the FQH effect. The conundrum is that no quantized FQH plateau is observed when it is the LLL that is half-filled, i.e., at $\nu = 1/2$ – see Fig. 1A. Yet, when the *second* LL is half-filled, resulting in a total filling factor $\nu = 5/2$, a robust FQH plateau is seen instead (Fig. 1B). In this section, we discuss a novel kind of gapless Fermi-liquid like state that was introduced to describe the $\nu = 1/2$, and its pairing instability that is believed to give rise to the exotic gapped state at $\nu = 5/2$.

Gapless composite fermion Fermi liquid in the half-filled Landau level

The $\nu = 1/2$ state finds a natural interpretation in the CF theory since at half-filling CFs see no residual magnetic field. Therefore, like electrons at zero field, CFs can form a Fermi liquid state, called the composite Fermi liquid (CFL) (Kalmeyer and Zhang, 1992; Halperin et al., 1993), which is gapless and thus does not lead to a FQH effect. The CFL is a markedly different state from the ordinary Fermi sea: in the LLL, there is no kinetic energy and interactions alone conspire to create an emergent Fermi-liquid. The wave function for the CFL at even-denominator fillings $\nu = 1/(2p)$ is obtained as the $n \rightarrow \infty$ limit of the wave function in Eq. (15):

$$\Psi_{1/(2p)}^{\text{CFL}} = \mathcal{P}_{\text{LLL}} \Phi^{\text{FL}} \Phi_1^{2p}, \Phi^{\text{FL}} \equiv \det \left[e^{i \vec{k}_i \cdot \vec{r}_m} \right]. \quad (16)$$

Halperin, Lee, and Read (HLR) Halperin et al. (1993) evaluated many properties of the CFL using a Chern–Simons field theory in which flux quanta are bound to electrons to turn them into CFs. This description is in qualitative agreement with numerous experiments that have verified the presence of the CFL (Kang et al., 1993; Willett et al., 1993; Goldman et al., 1994). In Section “Effective field theory” we shall discuss one particular experiment, namely the measurement of the CF Fermi wave vector using geometric resonance (Willett et al., 1999; Kamburov et al., 2014; Hossain et al., 2020), which has renewed the interest in the CFL state.

$\nu = 5/2$ state

The observation of a FQH state at the even-denominator filling $\nu = 5/2$ Willett et al. (1987) indicated that not all FQH states can be described using the ideas discussed in Section “Hierarchy and composite fermions”. Moore and Read Moore and Read (1991) identified conformal field theory (CFT) as an innovative tool for generating trial FQH wave functions (see Ref. Hansson et al. (2017) for an in-depth overview of this technique). Using a particular type of CFT, Moore and Read arrived at the following wave function for a state at $\nu = 1/2$:

$$\Psi_{1/2}^{\text{MR-Pf}} = \text{Pf} \left(\frac{1}{z_i - z_j} \right) \prod_{1 \leq i < j \leq N} (z_i - z_j)^2, \quad (17)$$

where the number of particles N is assumed to be even. The key component of this wave function is the Pfaffian – the antisymmetrized sum over pairs:

$$\text{Pf} \left(\frac{1}{z_i - z_j} \right) = \mathbb{A} \left(\frac{1}{z_1 - z_2} \frac{1}{z_3 - z_4} \dots \right), \quad (18)$$

where $\mathbb{A}$ represents the anti-symmetrization operator. The Pfaffian factor makes the overall wave function antisymmetric and therefore a valid trial state for electrons. As first suggested by Greiter et al. (1992), this wavefunction can provide a description of the experimental $\nu = 5/2$ resistance plateau, provided one assumes that the two lowest LLs of $\uparrow$ and $\downarrow$ spins are completely filled with electrons. Thus, Eq. (17) describes the correlations between fully spin-polarized electrons in the valence (half filled) SLL.

The Pfaffian factor introduces weak pairing between the CFs Read and Green (2000). Indeed, in the antisymmetrized product over pairs, we recognize the real-space form of the wave function describing a 2D Bardeen-Cooper-Schrieffer (BCS) superconductor. Thus, we can view Eq. (17) as the FQH analog of a $p_x + ip_y$ superconductor. The physical origin of pairing is due to the effective Coulomb interaction being less repulsive at short distances in the SLL compared to LLL. Thus, forming CFs overscreens the Coulomb repulsion resulting in a weak residual attractive interaction between them which leads to a pairing instability of their CFL. One

consequence of the electron pairing is an unconventional collective excitation on top of the Moore-Read ground state that was dubbed the “neutral fermion” mode (Bonderson et al., 2011; Möller et al., 2011).

The interest in the Moore-Read state was initially fueled by numerical simulations. Exact diagonalizations performed by Morf (1998) showed that the spin-polarized state at $\nu = 5/2$ had lower energy than any partially polarized or spin-singlet state, even in the absence of any Zeeman splitting. Furthermore, it was shown that the state was poised towards a compressible phase Rezayi and Haldane (2000) and can be easily pushed across the phase boundary by slightly varying the Hamiltonian in a way that mimics the effect of an in-plane magnetic field, accounting for experimental observations Eisenstein et al. (1990), Lilly et al. (1999), Pan et al. (1999). The correspondence between numerics and experiment has been made more quantitative by comparisons of the energy gap obtained from exact diagonalization Morf et al. (2002) and DMRG simulations Feiguin et al. (2008) with the one measured in experiments Kumar et al. (2010).

Anti-Pfaffian

While PH symmetry is exact for the FQH problem restricted to a single LL, the Moore-Read state in Eq. (17) is not invariant under PH transformation. The state obtained by PH conjugation applied to Eq. (17) is a topologically-distinct phase of matter that was named the “anti-Pfaffian” (aPf) (Levin et al., 2007; Lee et al., 2007). The two states have different thermal Hall responses and different edge excitations, which immediately leads to the question: which state describes the $\nu = 5/2$ ground state in the thermodynamic limit?

Distinguishing between the aPf and Moore-Read states has proven a considerable challenge. The key to discriminating between the two states is LL mixing, which explicitly breaks PH symmetry and lowers the energy of one of these states with respect to the other. Unfortunately, accurate modeling of LL mixing effects comes with many challenges, in particular its perturbative treatment Bishara and Nayak (2009), Sodemann and MacDonald (2013), Simon and Rezayi (2013), Pakrouski et al. (2015) cannot be rigorously justified. Nevertheless, as recently shown by Rezayi (2017), different theoretical approaches converge to the conclusion that LL mixing favors the aPf state.

On the other hand, experimental studies have detected signatures of $e/4$ quasiparticles at $\nu = 5/2$ using the interference of edge channels Willett et al. (2009). Shot noise measurements Dolev et al. (2010) and charge-sensing in the bulk using single-electron transistor Venkatachalam et al. (2011) have also reported evidence of $e/4$ quasiparticles. These results are consistent with both Moore-Read and aPf states. The dependence on voltage and temperature of the tunneling current was measured at a point contact in the $\nu = 5/2$ state and found to be consistent with the aPf state Radu et al. (2008). Furthermore, upstream neutral modes have been detected at $\nu = 5/2$ Bid et al. (2010), Dolev et al. (2011) which is consistent only with the aPf state.

Non-Abelian states

Contrasting the case of SLL with that of the LLL in Fig. 1A–B, one notices a few striking differences. One of the most prominent incompressible states in the SLL has an even denominator, $\nu = 2 + 1/2$ Willett et al. (1987) and its strength is roughly comparable with $\nu = 2 + 1/3$, which is expected to be analogous to the $\nu = 1/3$ Laughlin state in the LLL Balram et al. (2013). Moreover, FQH effect is also observed at $\nu = 2 + 3/8$ Xia et al. (2004), Kumar et al. (2010). Even the odd-denominator FQH states in the SLL appear out of order when compared with the LLL sequence: FQH effect has been observed at $1/3$ and $2/5$ in the LLL, but no FQH effect has been confirmed at $3/7$, $4/9$ and $5/11$ but evidence for a plateau at $2 + 6/13$ exists Kumar et al. (2010). To explain these unconventional fractions, different theoretical approaches have been put forward. A common theme in these approaches are quasiparticles with non-Abelian braiding statistics, qualitatively different from the Abelian anyons we encountered in Section “Incompressible fluids”.

Non-Abelian anyons and topological quantum computation

Beyond the paired ground state wave function, the quasihole excitations of the Moore-Read state in Eq. (17) are particularly interesting: they must be created in pairs and they have non-Abelian braiding statistics. Imagine that $2n$ quasiholes have been added to the Moore-Read state by increasing the magnetic flux by n flux quanta. In non-Abelian FQH states, fixing the configuration of the quasiholes does not result in a unique quantum state – instead, there is a degenerate manifold of states. For example, in the Moore-Read state the $2n$ -quasihole manifold is 2^{n-1} -fold degenerate and is spanned by some orthogonal basis $\{\psi_1, \psi_2, \dots, \psi_{2^{n-1}}\}$. The braiding of two quasiholes, depicted in Fig. 2C, acts as a unitary transformation on this subspace, $\psi_\alpha = \mathcal{U}_{\alpha\beta} \psi_\beta$ Nayak and Wilczek (1996). As matrices $\mathcal{U}$ do not generally commute, the quasiholes in the Moore-Read state obey ‘non-Abelian’ braiding statistics.

The degenerate states ψ_α can be interpreted as basis states of a logical qubit, and the quasihole braiding operations $\mathcal{U}$ can be mapped to the action of quantum gates Freedman et al. (2003). These operations are topologically protected at sufficiently low temperatures $k_B T \lesssim \Delta_{MR}$, where Δ_{MR} is the excitation gap of the Moore-Read state. This is because the qubit states are locally indistinguishable and any decoherence induced by local perturbations will be strongly suppressed. This idea of employing a topologically-protected manifold of non-Abelian FQH quasiholes to encode and manipulate a quantum bit is known as *topological quantum computation* Nayak et al. (2008).

While the prospect of avoiding the need for error correction in a quantum computer is of immense practical benefit, the particular system of Moore-Read anyons discussed above falls short of this goal as it is unable to perform so-called universal

quantum computation. The simplest FQH system capable of universal topological quantum computation is discussed in Section “ $\nu = 12/5$ state”. At this stage, however, topological quantum computation with FQH states remains a theoretical concept, although recent progress in FQH interferometry Willett et al. (2021) and Nakamura et al. (2020) paves the way to a potential demonstration of an operating FQH qubit. We note that special types of one-dimensional nanowires can host boundary excitations with properties reminiscent of Moore-Read anyons Kitaev (2001), offering a potentially more practical realization of topological quantum computation. The efforts towards topological quantum computation will rely critically on better understanding and better control of FQH excitations, which may be aided by STM techniques (Papić et al., 2018).

$\nu = 12/5$ state

Universal quantum computation can be performed with more complex types of anyons that emerge in the Read-Rezayi (RR) sequence of states (Rezayi, 1999). These non-Abelian states generalize the notion of pairing between pairs of particles in the Moore-Read state to a clustering of larger groups (three or more particles). The RR states occur at filling factors $\nu = k/(k+2)$, with $k = 1, 2$ being the Laughlin and Moore-Read states, respectively. The $k = 3$ RR state is a qualitatively new non-Abelian state hosting the so-called Fibonacci anyons. This state is often referred to as $\mathbb{Z}_3$ RR state because its wavefunction was originally constructed using a $\mathbb{Z}_3$ parafermion conformal field theory (Rezayi, 1999).

Experimental observation of the $\nu = 12/5$ FQH plateau by Xia et al. (2004) and subsequently Kumar et al. (2010) has generated much excitement due to the possibility that it may be described by the PH conjugate of the $\mathbb{Z}_3$ RR state. Numerical work Rezayi (1999) indicated that the Coulomb ground state at $\nu = 12/5$ is close to a phase transition between the Abelian CF state and the PH conjugate of $\mathbb{Z}_3$ RR state. More recent studies using DMRG Mong et al. (2017) have found that the ground state at $\nu = 12/5$ is fully spin-polarized and in the vicinity to a charge-density-wave ordered phase. The latter was found to be much more sensitive to LL mixing at $\nu = 13/5$ than at $\nu = 12/5$ Pakrouski et al. (2016), accounting for the absence of a quantized plateau at $\nu = 13/5$. Due to a much smaller gap in the $\nu = 12/5$ state and the scarcity of its experimental realizations, the definitive determination of its nature remains much more challenging compared to $\nu = 5/2$.

Other non-Abelian states

Previously mentioned RR states are a small subset of a family of states associated with the so-called Jack polynomials Feigin et al. (2002). As first realized by Bernevig and Haldane (2008), the wave function of many FQH states at filling factors $\nu = k/(k+r)$ can be identified with a single Jack polynomial, parametrized by integers k, r and a so-called “root” state. In the case $r = 2$ the Jacks coincide with the RR states discussed in Section “ $\nu = 12/5$ state”. An interesting case with $k = 2$ and $r = 3$ corresponds to the so-called “Gaffnian” state Simon et al. (2007b), which has inspired much theoretical work as a potential example of a gapless non-Abelian state Read (2009a). The recursive properties of the Jack polynomials impose a great deal of analytical structure on FQH wave functions, a fact that has been fruitfully employed in numerical computations (Bernevig and Regnault, 2009).

Bonderson and Slingerland (2008) constructed trial wave functions for many of the filling factors where FQH states have been observed in the SLL. The Bonderson-Slingerland approach obtains FQH wave functions as a product of the bosonic version of the Moore-Read state and a composite fermion state. In particular, this approach yields a state that is competitive with the (PH conjugate of) $\mathbb{Z}_3$ RR state at $\nu = 12/5$ (Bonderson et al., 2012). On the other hand, the observed filling factor $2 + 6/13$ Kumar et al. (2010) is not a part of this sequence. Other constructions, based on condensing non-Abelian quasiparticles of the Moore-Read state Hermanns (2010) or by taking products of the bosonic RR states with the Laughlin state Jolicœur (2007), have also been proposed. The hierarchical construction of Levin and Halperin (2009) may account for the FQH effect observed at filling $\nu = 2 + 6/13$. Somewhat surprisingly, the Levin-Halperin states turn out to be Abelian, even though they derive from a non-Abelian Moore-Read parent state. Most of these states, however, result in complicated wave functions that have not been systematically tested in numerical simulations.

Multicomponent fractional quantum Hall effect

Up to this point, our discussion was restricted to fully spin-polarized electrons, as is appropriate for the setting when the external magnetic field is large. It turns out that the Zeeman splitting E_Z (see Section “Introduction”) is strongly suppressed in GaAs: the ratio of E_Z to the Coulomb energy scale for a typical magnetic field $B = 9$ T is $\xi = E_Z/(e^2/(4\pi\epsilon\ell)) \approx 0.02$. Experimentally, it is possible to tune ξ by tilting the sample or introducing a parallel magnetic field, suppressing the g -factor using hydrostatic pressure (Leadley et al., 1997; Nicholas et al., 1998) or changing the 2DEG’s density. Therefore, for certain parameter regimes, it could be favorable for a fraction of the electrons to flip their spin leading to the formation of unpolarized states Chakraborty and Zhang (1984), Chakraborty (2000). We now turn our attention to such “multicomponent” FQH states where the internal degree of freedom allows the electrons to form new kinds of correlated states without analogs in single-layer FQH systems.

Apart from ordinary spin, the valley degree of freedom could also lead to multi-component FQHE and this plays a particularly important role in materials such as graphene. Here, we just mention that multi-component FQHE has been also observed in multi-valley semiconductor systems such as AlAs (Bishop et al., 2007; Padmanabhan et al., 2009). Furthermore, it has also been possible to fabricate two single-layer 2DEGs in close proximity to each other, such that the two layers assume the role of $\uparrow, \downarrow$ spin states. The advantage of studying such bilayer FQH systems is the enhanced tunability of the interactions: one can vary both the

tunneling Δ_{SAS} between the two layers, as well as the effective interlayer distance d/ℓ . Note that, conveniently, the physical distance d can be fixed and one varies ℓ by tuning the overall magnetic field (while also adjusting the electron density to remain at the same filling factor). The parameter d/ℓ directly modifies the interlayer Coulomb interaction, which has a strong effect on many-electron states. In experiment, two main architectures were pursued: wide single quantum wells in which electrostatic effects produce a ground subband wave function with a pronounced dumbbell shape [Suen et al. \(1992\)](#) and true double quantum wells consisting of two thin GaAs layers embedded in the alloy $\text{Al}_x\text{Ga}_{1-x}\text{As}$ ([Eisenstein et al., 1992](#)).

Theoretical understanding of multicomponent FQH states is guided by Halperin's generalization of the Laughlin wave function in Eq. (10) to FQH systems with a discrete internal quantum number [Halperin \(1983\)](#). Halperin's states are parametrized by non-negative integers m , m' and n and their wave functions are given by

$$\Psi^{(m,m',n)} = \prod_{i<j} (z_i - z_j)^m \prod_{i<j} (w_i - w_j)^{m'} \prod_{i,j} (z_i - w_j)^n, \quad (19)$$

where $\{z_k\}$ and $\{w_k\}$ are the coordinates of the electrons in the "top" and "bottom" layer (or spin state), respectively. The exponents m and m' must be odd integers due to Pauli exclusion principle, while n does not have such a restriction. Moreover, because intra-species correlations are typically stronger than inter-ones we must have $m, m' \geq n$. The state in Eq. (19) corresponds to the filling factor $\nu_T = (m + m' - 2n)/(mm' - n^2)$. Most of the time, one is interested in the balanced case where the two layers or spin species are equivalent, i.e., $m = m'$, which can be physically interpreted as each layer forming a $\nu = 1/m$ Laughlin state, with interlayer correlations controlled by exponent n .

We note that the Halperin (m, m, n) states can be generalized to bilayer CF states, where the $\nu = 1/m$ Laughlin states in each layer are replaced by a Jain state [Scarola and Jain \(2001\)](#). Furthermore, in the case of spin, the CF wave function in Eq. (15) can be directly generalized to accommodate the spin degree of freedom by filling up $n_\uparrow$ LLs with $\uparrow$ -spin electrons (and similarly $n_\downarrow$ LLs filled with electrons of opposite spin) [Wu et al. \(1993\)](#). Depending on $n_\uparrow$ and $n_\downarrow$, states with full or partial spin polarization can be readily constructed.

Spinful systems

In single-layer FQH systems, as ξ is varied, transitions between states with different spin polarization can take place and have been extensively studied in experiment, see an illustrative example in [Fig. 6A](#). For example, at $\nu = 4/7$, three CF states can be constructed: (a) fully polarized with $n_\uparrow = 4$ and $n_\downarrow = 0$, (b) partially polarized with $n_\uparrow = 3$ and $n_\downarrow = 1$, and (c) spin-singlet with $n_\uparrow = 2 = n_\downarrow$. At large ξ , the ground state is fully polarized. As ξ is lowered, the fully polarized state transitions to a partially polarized state and eventually at small ξ goes into a spin-singlet state. At the Laughlin fractions, even at zero Zeeman splitting, the ground state is fully spin polarized due to exchange interactions, an effect that has been dubbed quantum Hall ferromagnetism [Sondhi et al. \(1993\)](#).

In the presence of spin, PH symmetry relates states at ν to $2 - \nu$. Experimentally in GaAs, spin transitions have predominantly been studied at fractions in the range $1 < \nu < 2$ ([Clark et al., 1989](#); [Du et al., 1995](#)). The reason for this is at larger fillings, the magnetic field is smaller and thus the starting Zeeman energy is lower which allows access to the least polarized states. Then by tilting the sample, Zeeman energy can be increased and states with higher polarizations can be accessed. The spin phase diagram of the Jain fractions has been worked out in detail both theoretically ([Park and Jain, 1998](#); [Balram et al., 2015a](#)) and experimentally ([Du et al., 1995](#); [Kukushkin et al., 1999](#); [Liu et al., 2014](#)) and these are in semi-quantitative agreement with each other.

In the presence of spin, the excitations of fully polarized ground states can also change character. In Sections "Magnetoroton excitation" and "Composite fermions" we discussed excitations which are spin-conserving. However, at low values of ξ , the lowest-lying excitation could involve a spin-flip. At the Laughlin fractions, this lowest-lying spin-flip mode, termed the spin-wave, has energy identical to the Zeeman splitting in the long-wavelength limit [Kallin and Halperin \(1984\)](#). In the fully polarized CF states the spin-wave mode has a roton minimum [Mandal and Jain \(2001\)](#) which lies below the ground state at zero-Zeeman splitting. The presence of these low-lying excitations is indicative of the fact that as ξ is lowered the fully polarized ground state could become unstable giving way to another state with lower polarization.

More exotic excitations involving spin-flip such as skyrmions ([Sondhi et al., 1993](#); [Fertig et al., 1994](#)), that carry a topological spin texture, can also be stabilized at low values of ξ in the vicinity of a Laughlin fraction. These skyrmions can be viewed as CF particles or CF holes dressed by spin waves. The exchange interaction between CFs is much weaker than that between electrons, so it is a lot harder to realize and detect fractional skyrmions compared to their integer counterparts. Nevertheless, Zeeman-energy dependence of certain excitations does point to the existence of neutral spin-textures in the vicinity of $\nu = 1/3$ which have been interpreted as arising from pair(s) of skyrmions and anti-skyrmions [Groshaus et al. \(2008\)](#). More direct evidence for their existence has been obtained from the measurement of the binding energy of fractional skyrmions in the vicinity of $\nu = 1/3$ using light-scattering experiments ([Balram et al., 2015b](#)).

Bilayer systems

The first experimental evidence for unusual states in bilayer systems was the observation of a quantized Hall plateau at $\nu_T = 1/2$ in a bilayer system with $d/\ell \lesssim 3$, in stark contrast to a single-layer FQH system at the same filling ([Suen et al., 1992](#); [Eisenstein et al., 1992](#)). Numerical calculations ([Chakraborty and Pietiläinen, 1987](#); [Yoshioka et al., 1989](#); [He et al., 1993](#)), verified the existence of an incompressible state and identified it with the (3,3,1) Halperin state in Eq. (19). More recently, there has been some renewed interest in the $\nu_T = 1/2$ two component systems [Shabani et al. \(2009, 2013\)](#) due to the possible transition into the Moore-Read state

Fig. 6 Multicomponent FQH effects. (A) Transitions between CF states with different spin polarization (solid dots) as in-plane magnetic field is varied. The lines are fits from the free CF theory, with the g^* factor and the effective mass m^* treated as empirical parameters. B_{eff} is the effective magnetic field. (B) Phase diagram of GaAs wide quantum wells at $\nu_T = 1/2$ as a function of d/ℓ and $\alpha = \Delta_{\text{SAS}}/(e^2/4\pi\epsilon_l\ell)$. Region corresponding to an incompressible FQH state is shaded in yellow. The interlayer distance d and layer width ℓ are estimated numerically from the self-consistent charge distribution. (C) Exciton condensation in $\nu_T = 1$ bilayers. Tunneling conductance dI/dV vs interlayer voltage V for a range of total densities N_T , corresponding to $1.6 \lesssim d/\ell \lesssim 2.3$. Trace A, at the highest density, shows a deep suppression of the tunneling near zero bias. By trace D, the lowest density of the four shown, this suppression has been replaced by a tall peak, signalling exciton condensation. The vertical scale is the same for all traces. (A) Data from Ref. Du RR, Yeh AS, Stormer HL, Tsui DC, Pfeiffer LN, and West KW (1995) Fractional quantum Hall effect around Composite fermions with a spin. *Physical Review Letters* 75: 3926–3929, doi: 10.1103/PhysRevLett.75.3926. (B) Figure reproduced from Ref. Shabani J, Liu Y, Shayegan M, Pfeiffer LN, West KW, and Baldwin KW (2013) Phase diagrams for the stability of the fractional quantum Hall effect in electron systems confined to symmetric, wide GaAs quantum wells. *Physical Review B* 88: 245413, doi: 10.1103/PhysRevB.88.245413. (C) Figure reproduced from Ref. Spielman IB, Eisenstein JP, Pfeiffer LN, and West KW (2000) Resonantly enhanced tunneling in a double layer quantum Hall ferromagnet. *Physical Review Letters* 84: 5808–5811, doi: 10.1103/PhysRevLett.84.5808.

as tunneling is increased Ho (1995), Peterson et al. (2010), Zhao et al. (2021). An example of the phase diagram in a wide quantum well at $\nu_T = 1/2$ is reproduced in Fig. 6B.

Perhaps the most remarkable bilayer quantum Hall phenomenon is the exciton condensation observed at total filling $\nu_T = 1$ (Spielman et al., 2000; Tutuc et al., 2004). The key to demonstrating the existence of excitons was the measurement of interlayer tunneling conductance at zero bias, which revealed a sharp change in the behavior depending on d/ℓ . When d/ℓ is sufficiently small, one observes a pronounced Josephson-like peak Spielman et al. (2000), see Fig. 6C. The peak reflects the fact that there is no energy cost associated with the transfer of an electron from one layer to the other. Furthermore, one can also probe the system in a so-called “drag” configuration, where the current is driven through one of the layers and the voltage drop is measured in the other layer. In the exciton phase, the Hall drag resistance becomes accurately quantized (Kellogg et al., 2002; Tutuc et al., 2009).

Theoretical explanation of these experimental findings is provided by the Halperin (1,1,1) state of Eq. (19). In this state, each electron is a coherent linear superposition of the two layers Fertig (1989) where the relative phase ϕ is arbitrary and the same for all electrons. Such a state is ferromagnetically ordered in the $x - y$ plane, inclined by the angle ϕ relative to the x -axis and spontaneously chosen by the system. As a consequence of spontaneous U(1) symmetry breaking, the system acquires a gapless Goldstone mode – a linearly dispersing pseudospin wave Moon et al. (1995), which was detected in Ref. Spielman et al. (2001).

While the properties of the $\nu_T = 1$ bilayer have been well-understood in the limits of small and large d/ℓ , the nature of the transition at some critical d_c/ℓ and a possibility of intermediate phases remain the subject of on-going work (Möller et al., 2008; Milovanović et al., 2015; Zhu et al., 2017; Lian and Zhang, 2018; Wagner et al., 2021).

Recent developments

In recent years the interest in FQH phases has expanded beyond topology into broader investigations of geometric effects and quantum entanglement. Moreover, there has been a resurgence of interest in the parton description of FQH states and effective field theories that incorporate geometric effects and particle-hole symmetry. This section is an overview of these recent developments in the field.

Parton theory

Parton theory was initially introduced as a generalization of CF theory to describe a wider class of states Jain (1989b). In the Parton theory, one imagines splitting the electron into k (an odd integer) fictitious sub-particles called *partons*. To obtain an incompressible state, each of the partons is placed in an IQH state (or in general, any known incompressible state), resulting in the wave function:

$$\Psi_v^{n_1 n_2 \dots n_k} = \mathcal{P}_{\text{LLL}} \prod_{\beta=1}^k \Phi_{n_\beta}, \quad (20)$$

where β labels the parton species. The parton state described by the wave function given in Eq. (20) is referred to by the shorthand notation “ $n_1 n_2 \dots n_k$.” The partons are unphysical entities so they need to be glued back together to recover the physical electrons. At the level of wave functions, this gluing procedure is implemented by setting the different parton species coordinates equal to the electron coordinate (each Φ_{n_β} in Eq. (20) is built up of all the electronic coordinates.). All the partons are exposed to the same external magnetic field as the underlying electrons and each parton species has the same density as that of the electrons. Therefore, the charge of the β parton $q_\beta = -e\nu/n_\beta$. The constraint that the sum of the parton charges should add to that of the electron relates the parton fillings to the electronic filling, i.e., $\sum_{\beta=1}^k q_\beta = -e \Rightarrow \nu = [\sum_{\beta=1}^k n_\beta^{-1}]^{-1}$.

Looking back at the wave functions in Eqs. (10) and (15), it follows that all of the Abelian Laughlin and Jain states are parton states. The parton theory can also describe non-Abelian states. In general, a parton state with a repeated factor of n , with $|n| \geq 2$ hosts non-Abelian excitations Wen (1991). The simplest non-Abelian parton state – the 221 state Jain (1989b) at $\nu = 1/2$ – can be interpreted as an f -wave superconductor of CFs Faugno et al. (2019). Recent identification of a parton state that lies in the same universality class as the aPf state but provides a better microscopic representation of the exact Coulomb ground state at $5/2$ Balram et al. (2018) has led to a resurgence of interest in partons. Furthermore, it has been shown that certain high-energy excitations of the states in the Jain sequence lie beyond the scope of the CF theory Nguyen et al. (2022) while they lend themselves to a description in terms of partons Balram et al. (2022). At this stage, the parton theory promises to provide a unified framework for describing all of the quantum Hall effects.

Effective field theory

As we mentioned in Section “Incompressible fluids,” many of the exotic properties of FQH states originate from the emergent Chern-Simons gauge field. Based on this idea, a field-theoretic approach to FQH systems was pioneered by Zhang et al. (1989) who showed, using a Chern-Simons field theory, that the FQH effect at Laughlin fractions can be mapped onto a superfluid of composite bosons. Alternatively, the Chern-Simons field theory of CFs was introduced by Lopez and Fradkin (1991) and further developed by Halperin et al. (1993) and extended via a Hamiltonian formalism by Murthy and Shankar (2003). Detailed treatment

of these theories is beyond the scope of the current chapter. Below we discuss two important recent developments in formulating an effective field theory of FQH systems: the role of PH symmetry and geometrical degrees of freedom.

The interest in the field-theoretic description of FQH systems, in particular in the role played by PH symmetry, has recently been renewed by geometric resonance experiments, which probe the radius of the cyclotron orbit of CFs. A series of measurements [Kamburov et al. \(2014\)](#) and [Hossain et al. \(2020\)](#) have shown that the CF Fermi wave vector k_F^* is determined by the density of minority carriers in the LLL, i.e., the CF Fermi wave vector is set by the electron density for $\nu \leq 1/2$ and by the hole density for $\nu > 1/2$. In other words, the quantity $k_F^* \ell$ is PH-symmetric. The state that underpins the HLR theory does not reside entirely in the LLL and thus it does not obey PH symmetry manifestly. This puzzle is resolved by going beyond the mean-field level, where it has been shown that the HLR theory produces results that are PH-symmetric and consistent with experiment ([Wang et al., 2017](#)).

In parallel, [Son \(2015\)](#) proposed a field theory that is valid in the vicinity of half-filling and has a built-in PH symmetry. In Son's theory, CFs are Dirac particles whose density is controlled by the external magnetic field as opposed to by the density of electrons. The PH symmetry of electrons acts as a time-reversal symmetry on Dirac CFs. This results in an absence of $2k_F$ back-scattering that was subsequently observed in DMRG simulations [Geraedts et al. \(2017\)](#), providing evidence in favor of Son's theory. One can ask how different are the predictions of Son's theory from that of the HLR theory? Surprisingly, it turns out that the refined version of HLR theory is consistent with Son's theory on many aspects ([Wang et al., 2017](#)).

Interestingly, Son's construction suggests a PH-symmetric gapped state at half-filling – dubbed the “PH symmetric Pfaffian” (PH-Pf). The PH-Pf state is topologically distinct from both the Moore-Read state and a Pf state. Intriguingly, recent thermal Hall [Banerjee et al. \(2018\)](#) and heat transport measurements [Dutta et al. \(2021\)](#) at $\nu = 5/2$ appear to be consistent with only the PH-Pf order. Two candidate wave functions for the PH-Pfaffian phase have been considered in the literature [Jolicœur \(2007\)](#) and [Zucker and Feldman \(2016\)](#), both with a high degree of PH symmetry. The two wave functions also have high overlaps with each other for small systems indicating that they likely describe the same phase. However, numerical studies find no evidence for the existence of the PH-Pf phase in clean systems ([Balram et al., 2018](#); [Mishmash et al., 2018](#)). Understanding the heat transport measurements at $\nu = 5/2$ in light of the numerical results presents one of the foremost challenges in the field.

Apart from PH symmetry, it has recently become apparent that any effective field theory capable of capturing dynamical response of FQH phases must include the *geometric* degrees of freedom FQH systems, which are beyond the remit of purely topological field theories. An important example of a geometric property is the Wen-Zee shift [Wen and Zee \(1992\)](#), related to the response function known as Hall viscosity ([Avron et al., 1995](#); [Read, 2009b](#)). This has highlighted the need for a deeper understanding of “quantum geometry” in FQH fluids [Haldane \(2011\)](#). The quantum geometry is associated with the magnetoroton (GMP) collective excitation of FQH fluids in the long-wavelength limit (cf. Section “Magnetoroton excitation”). In this limit, the GMP mode can be interpreted as a quadrupolar density-wave deformation of the ground state and it has been incorporated into a gravitational field theory in the form of a spin-2 field coupled to an ambient geometry ([Gromov and Son, 2017](#)). Occasionally, this emergent spin-2 degree of freedom is also referred to as “FQH graviton” ([Yang et al., 2012a](#); [Golkar et al., 2016](#); [Liou et al., 2019](#)). The dynamics of the spin-2 modes [Liu et al. \(2018\)](#) can be induced by mass anisotropy [Yang et al. \(2012b\)](#), [Wang et al. \(2012\)](#), and [Chazaryan and Chakraborty \(2015\)](#) or by tilting the magnetic field ([Chakraborty and Pietiläinen, 1989](#); [Papić, 2013](#)). In gapless CFL states, the geometric effects manifest through the shape of the Fermi contour ([Gokmen et al., 2010](#); [Jo et al., 2017](#)). The investigation of geometric responses of FQH systems to the variations of ambient geometry represents an active research direction ([You et al., 2014](#); [Bradlyn and Read, 2015](#); [Can et al., 2014](#)).

Entanglement-based approaches

Quantum entanglement has recently emerged as a powerful probe of topological order. One characterizes entanglement by evaluating the system's reduced density matrix, obtained by partitioning the FQH system into two halves and tracing out one of the subsystems. As first shown by Li and Haldane [Li and Haldane \(2008\)](#), the spectrum of the reduced density matrix – the “entanglement spectrum” – contains information about the edge excitations of the system and it can be used to infer the CFT that governs the FQH state.

For FQH wave functions such as the Laughlin or Moore-Read, the number of levels in the entanglement spectrum as a function of momentum in the subsystem becomes universal as the subsystem size increases and it corresponds to the edge spectrum of the corresponding CFT. This “bulk-boundary” correspondence suggests that the bulk of the system and the physical edge are related to each other [Dubail et al. \(2012\)](#). On the other hand, the entanglement spectrum of a physical ground state of the Coulomb interaction is found to contain both a universal CFT part and a non-universal part. The latter is separated by a “entanglement gap” [Thomale et al. \(2010\)](#), which is argued to remain finite in a gapped FQH phase, signaling the robustness of topological order. The entanglement spectrum has found broad use as a tool for topological characterization of phases of matter beyond FQH states discussed in this chapter.

Finally, as first shown by [Zaletel and Mong \(2012\)](#), certain FQH wave functions that can be expressed as correlators of a CFT can also be turned into a matrix-product state (MPS) if one picks the basis of LL orbitals on a cylinder geometry. This leads to a significant advantage in extracting physical properties from FQH wave functions. Exact MPS representations have been found for many states discussed above [Estienne et al. \(2013\)](#). Beyond studies of FQH wave functions, the MPS method has been generalized into a variational density-matrix renormalization group scheme for approximating ground states of realistic systems with Coulomb interactions [Zaletel et al. \(2013\)](#).

Table 1 Summary of topological properties of main single-component FQH states considered in this chapter.

Filling, ν	State	Shift, S	Chiral central charge, c_-	Quasiparticle charge, Q_{qp}	GSD
$1/(2p+1)$	1^{2p+1} , Laughlin	$2p+1$	1	$1/(2p+1)$	$2p+1$
$n/(2pn \pm 1)$	$(\pm n)1^{2p}$, Jain	$(\pm n) + 2p$	$1 \pm (n-1)$	$1/(2pn \pm 1)$	$2pn \pm 1$
$1/(2p)$	Moore-Read	$2p+1$	$3/2$	$1/(4p)$	$6p$
$1/(2p)$	$2^2 1^{2p+1}$, anti-Pfaffian	$2p-3$	$-1/2$	$1/(4p)$	$6p$
$2/5$	$2^3 1^4$, anti- $\mathbb{Z}_3$ Read-Rezayi	-2	$-4/5$	$1/5$	10

For the states captured by parton theory, we also show their parton label according to Eq. (20). Some of the quantities in this Table can be accessed experimentally: filling factor ν is related to the electrical Hall resistance R_{xy} via Eq. (6), chiral central charge c_- is related to the thermal Hall conductance κ_{xy} via Eq. (8) (any filled LLs provide an additional contribution), Q_{qp} is the charge of fundamental quasiparticle in units of the electron charge which can be accessed via shot-noise experiments or by charge-sensing using a single-electron transistor, the shift S on the sphere is related to the Hall viscosity η_H . The ground state degeneracy (GSD) is quoted for the torus. The composite fermion Fermi liquid (CFL) is not expected to carry a quantized κ_{xy} since its bulk is gapless.

Conclusion

In this chapter we presented an introduction to the FQH effect observed in semiconductor systems. While it was impossible to give a historically exhaustive account of the entire field, we hope that the multitude of examples illustrates the great richness of emergent many-body phenomena and the diversity of approaches that have been developed over the years in order to understand the novel physics associated with the FQH effect. To emphasize this diversity, our presentation has focused on explaining the experimental observations through model states, which distil the essence of FQH physics into elegant wave functions that can be studied either analytically or in computer simulations. Thus, we conclude by presenting a summary of the properties of the main single-component FQH phases discussed above in Table 1. The table lists some key topological quantum numbers that can be used to characterize an FQH phase, as discussed in Section “Incompressible fluids”. Some of these quantities are accessible in experiments and others in numerics.

Throughout this chapter, we have highlighted many open problems and research directions that remain particularly active at the time of writing (early 2022). We note in particular that the material realizations of the FQH effect continue to expand, most notably in the context of graphene and other van der Waals materials, fractional Chern insulators, as well as synthetic quantum simulators based on ultracold atoms and superconducting qubit arrays. We purposefully avoided discussing alternative material realizations of the FQH effect, as some of them are discussed in other chapters of this encyclopedia. These new material platforms may offer additional pathways to testing some of the theoretical ideas discussed above, while they will undoubtedly pose new puzzles to be understood. For a research field that is now four decades old, the FQH effect remains a remarkably active source of exciting new physics.

Acknowledgments

We would like to thank Gabor Csathy and Wei Pan for generously sharing their experimental data that we plotted in Fig. 1. The authors express their deep sense of gratitude to all of their collaborators over the years, without whom this chapter would not have been possible. A. C. B. acknowledges the Science and Engineering Research Board (SERB) of the Department of Science and Technology (DST) for financial support through the Start-up Grant SRG/2020/000154. A. C. B. and Z. P. thank the Royal Society International Exchanges Award IES\R2\202052 for funding support. Some of the numerical calculations reported in this work were carried out on the Nandadevi supercomputer, which is maintained and supported by the Institute of Mathematical Science’s-High-Performance Computing Center. Z. P. acknowledges support by the Leverhulme Trust Research Leadership Award RL-2019-015.

Abstract

The fractional quantum Hall effect is a very particular manifestation of electronic correlations in two-dimensional systems in a strong perpendicular magnetic field. It arises as a consequence of a strong Coulomb repulsion between electrons in the same Landau level that conspires with a particular chirality of the electronic states. This chirality is inherited from the classical cyclotron motion, i.e., a particular sense of electronic rotation due to the orientation of the magnetic field. The specificity of the FQHE in graphene consists of a fourfold spin-valley degeneracy inherited from the electronic bands in the vicinity of the Fermi level. The relevant Coulomb interaction respects this SU(4) symmetry, and one is therefore confronted with a generic four-component fractional quantum Hall effect, as well as with other correlated four-component phases, such as spin-valley ferromagnetic states. The present article aims at a—mainly theoretical—discussion of these exotic phases, in comparison with experimental evidence for them.

Key points

- The fractional quantum Hall effect arises in partially filled degenerate Landau levels as a consequence of strong repulsive interactions.
- In graphene, the fractional quantum Hall effect reflects an approximate SU(4) symmetry because the twofold spin degeneracy is accompanied by a twofold valley degeneracy that is approximately respected by the relevant Coulomb repulsion between the electrons.
- In addition to its SU(4) symmetry, the effective interaction potential between electrons in graphene Landau levels is specific as compared to that in usual two-dimensional electron systems (semiconductor heterostructures) as a consequence of the overlap between the spinorial wave functions.
- The SU(4) symmetry of interacting electrons in graphene Landau levels is also relevant in the formation of generalized quantum-Hall ferromagnetic states at integer filling factors, as well as in the description of spin-valley skyrmions and magnons.
- Similarly to the generalized quantum-Hall ferromagnetic states, the fractional quantum Hall states in graphene are characterized by their (partial) spin-valley polarization, and some of them support magnon-type excitations and skyrmions due to a spontaneously broken spin-valley SU(4) symmetry.
- In higher Landau levels, the fractional quantum Hall effect coexists with other correlated electronic states (electronic crystals), and the alternation between fractional quantum Hall and crystalline states upon variation of the filling factor is at the origin of a reentrant integer quantum Hall effect.

Introduction

The quantum Hall effect is a universal phenomenon of two-dimensional (2D) electronic systems submitted to a strong magnetic field. First discovered in 1980 by [Klitzing et al. \(1980\)](#), who received the Nobel Prize in Physics for this discovery in 1985, the effect consists of the appearance of plateaus in the Hall resistance accompanied by a vanishing longitudinal resistance (for a sketch of the setup and a characteristic measurement, see [Fig. 1](#), where the associated conductances are plotted). Most saliently, the plateaus in the

Fig. 1 Characteristic transport signatures of the quantum Hall effect in graphene. The Hall (blue) and the longitudinal (red) conductances are plotted as a function of the electronic density, which is proportional to the gate voltage V_g , at fixed magnetic field ($B = 15$ T) and temperature $T = 0.3$ K. The inset shows the measurement setup in which a current is driven through the system via the contacts S (source) and D (drain). The longitudinal conductance is measured between the contacts connected by the blue line, while the Hall conductance is measured between the contacts connected by the red line. The numbers indicate the value j of the plateau in the Hall conductance $\sigma_{xy} = R_H^{-1} = e^2 j/h$. One clearly distinguishes the integer plateaus of the IQHE (integer numbers below the Hall-conductance curve) from the FQHE plateaus at fractional values of j (numbers above the Hall curve). Adapted from Ribeiro-Palau R, Chen S, Zeng Y, Watanabe K, Taniguchi T, Hone J, Dean CR (2019) High-quality electrostatically defined hall bars in monolayer graphene. *Nano Letters* 19: 2583–2587. <https://doi.org/10.1021/acs.nanolett.9b00351>.

Hall resistance indicate an extremely precise quantization, $R_H = h/e^2 j$, in terms of the inverse quantum of conductance $G_0 = e^2/h$ and an integer number j . It is the manifestation of the so-called Landau quantization according to which 2D electrons in a strong magnetic field have a discrete energy spectrum with highly degenerate energy levels (Landau levels, LLs). Soon after this discovery, D. Tsui and H. Störmer observed the fractional brother of the effect (Tsui et al., 1982): instead of an integer in the case of the so-called *integer quantum Hall effect* (IQHE), the number j can be a fractional one, whence the name *fractional quantum Hall effect* (FQHE). It became soon clear that the effect requires strong electronic interactions that govern the behavior of electrons inside a partially filled LL and that force the electrons to form an incompressible electron liquid at particular values of the filling factor $\nu = n_{el}/n_B$, which denotes the filling of the LLs. It is the ratio between the electronic density n_{el} and the density of flux quanta $n_B = eB/h$ threading the 2D system. A first approach to describe the FQHE was provided by Laughlin (1983), who proposed trial wave functions for the electron liquids at odd-integer filling factors $\nu = 1/(2s + 1)$, in terms of the integer s . The in-built correlations of these wave functions turned out to be favorable for the minimization of the mutual Coulomb repulsion between the electrons, and he shared the 1998 Nobel Prize in Physics with Tsui and Störmer for the discovery and description of the FQHE. One of the most exotic aspects of these electron liquids is certainly that of their quasiparticle excitations, which have fractional charge as it was first theoretically shown by Laughlin (1983) and later experimentally proven in particular transport experiments. In the latter the so-called shot-noise was measured, which is proportional to the (fractional) charge (de Picciotto et al., 1997; Saminadayer et al., 1997). Associated with this fractional charge and the 2D nature of the system, these quasiparticles obey furthermore fractional statistics: they are anyons, i.e., neither bosons nor fermions, and the identification of fractional statistics remains an important topic of today's research in condensed quantum matter (see also the chapter by M. Greiter and F. Wilczek), with recent breakthrough both in interference (Nakamura et al., 2020) and transport measurements (Bartolomei et al., 2020).

While the observed states at $\nu = 1/3$ and $\nu = 1/5$ could indeed be understood in terms of Laughlin's wave function, a plethora of states at other partial filling factors has since been observed with the continuous increase of the sample quality in GaAs heterostructures. In order to account for those on a theoretical level, Laughlin's wave function has been generalized in several manners, the most noteworthy of which are Jain's composite fermion (CF) wave functions (Jain, 1989) that account for the observation of states at $\nu = p/(2sp + 1)$ —the FQHE can then be seen as an IQHE of these CFs that populate p CF LLs—Halperin's wave functions (Halperin, 1983) which account for states that are not or only partially spin-polarized, as well as the Pfaffian wave function (Moore and Read, 1991; Greiter et al., 1991), which describes a FQHE in half-filled LLs that has been observed at $\nu = 5/2$ and $7/2$ (Willett et al., 1987) in the first excited LL. Most interestingly, the quasiparticles of the Pfaffian state are a particular type of anyons: they are *non-Abelian* anyons, in which case exchanges of more than two quasiparticles do not commute, and they are expected to play a relevant role in possible quantum computation (Kitaev, 2003). (For more information about the FQHE in general, see the chapter by Z. Papić and A. C. Balam.)

The mechanical isolation of graphene in Novoselov et al. (2004) provided the condensed-matter-physics community with a novel 2D electronic system and has ever since been heavily studied because of its unexpected electronic properties and its remarkable relation with relativistic quantum mechanics. A milestone experiment in graphene research was the observation of a particular version of the IQHE in 2005 by two groups, that of A. K. Geim at Manchester University and that of P. Kim at Columbia University (Novoselov et al., 2005; Zhang et al., 2005). The relevance of this discovery is twofold. First, it confirmed the above-mentioned universality of the effect since graphene is a largely different 2D electron system as compared to the usual ones formed at semiconductor interfaces. Second, the particular filling-factor values $\nu = \pm 2(2n + 1)$, at which the effect manifests itself, is a fingerprint of the relativistic quantum-mechanical behavior of electrons in graphene that are described in terms of a Dirac rather than the usual Schrödinger equation of quantum mechanics. (For an introduction to the physics of graphene, see the chapter by E. McCann.)

As compared to the original discoveries of the quantum Hall effects in the 1980s, it took relatively longer to observe the FQHE in graphene, which was equally expected because of the universality of the phenomenon. First experimental indications of a FQHE at $\nu = \pm 1/3$ were found in 2009 in freestanding graphene, where the original substrate on which the graphene sheet had been posed was etched away (Du et al., 2009; Bolotin et al., 2009). A true breakthrough was achieved in 2011 with the use of clean hexagonal boron-nitride (h-BN) flakes as a substrate that increased considerably the electronic mobility in graphene. This increase of the mobility allowed for the observation of a large amount of FQHE states (Dean et al., 2011), similarly to the effect in the more conventional 2D electron systems in semiconductor heterostructures.

The present article mainly aims at responding at the following question: what are the main differences with respect to the FQHE in conventional 2D electron systems? In analogy with the IQHE, whose particular manifestation in graphene can be understood in terms of the relativistic nature of graphene's electrons, is there something such as a relativistic version of the FQHE? This was indeed a central issue in the theoretical discussions about the FQHE in graphene before its experimental discovery. After a short reminder of LL quantization in graphene and the IQHE in section "Landau levels and the integer quantum Hall effect in graphene", section "Electrons in a single Landau level" introduces the basic properties of the electron dynamics in a single LL from a theoretical point of view. It is the basis for understanding the appearance of correlated phases, as it is discussed in section "Correlated electronic phases in partially filled Landau levels in graphene", not only the FQHE states (section "Fractional quantum Hall states"), but also a particular form of spin-valley quantum Hall ferromagnetism the polarization in which does not only concern the usual electron spin but also another twofold (valley) degree of freedom (section "Spin-valley quantum Hall ferromagnets"), and electron crystalline phases (section "Electron crystals").

Landau levels and the integer quantum Hall effect in graphene

Landau quantization denotes the formation of discrete levels into which the kinetic energy of 2D electrons is quenched in the presence of a strong perpendicular magnetic field. It was first treated theoretically by L. Landau in 1930 for free non-relativistic particles with electric charge¹ $-e$ that, in the absence of a magnetic field, have a quadratic dispersion relation, i.e., a quadratic dependence of their energy on their wave vector $\mathbf{k}$. In a typical condensed-matter system, where one deals with electrons in a periodic potential created by the atoms forming the crystal, this situation arises generically in the vicinity of the bottom of an electronic band that is described by a Bloch Hamiltonian $H(\mathbf{k})$. Elementary band theory shows that in the vicinity of the band bottom, where the Fermi level resides, e.g., in the widely used semiconductor GaAs, the Bloch Hamiltonian is $H(\mathbf{k}) \simeq \hbar^2 |\mathbf{k}|^2 / 2m$, i.e., precisely that of a free non-relativistic particle in terms of the band mass m . Landau quantization is then obtained by replacing the momentum $\mathbf{p} = \hbar \mathbf{k}$ by its gauge-invariant form $\mathbf{p} + e\mathbf{A}(\mathbf{r})$, where $\mathbf{A}(\mathbf{r})$ is the vector potential at the position $\mathbf{r}$, which yields the magnetic field $\mathbf{B} = \nabla \times \mathbf{A}(\mathbf{r})$. The usual quantum-mechanical non-commutativity of position and momentum, $[x, p_x] = [y, p_y] = i\hbar$, then gives the energy spectrum

$$E_n = \hbar \omega_C \left(n + \frac{1}{2} \right), n = 0, 1, 2, \dots \quad (1)$$

of the harmonic oscillator, in terms of the cyclotron frequency $\omega_C = eB/m$. In contrast to the usual one-dimensional harmonic oscillator, the energy levels (the LLs) are highly degenerate because the system remains 2D. This degeneracy is related to translation symmetry in the case of a homogeneous magnetic field. Even if this symmetry is, strictly speaking, broken by the position-dependent vector potential entering in the Hamiltonian, translation symmetry is to some extent restored if we consider the electron dynamics from a (semi-)classical point of view. Indeed, the electrons are forced to perform a circular cyclotron motion around a position $\mathbf{R} = (X, Y)$ —the *guiding center*—that is a constant of motion, in contrast to the momentum that constantly changes its direction. Most saliently, the two components of the guiding center do not commute, $[X, Y] = i l_B^2 \text{sgn}(B)$, in terms of the magnetic length $l_B = \sqrt{\hbar/e|B|}$ and the orientation of the magnetic field, $\text{sgn}(B) = B/|B|$. This has two consequences: first, each quantum state in a LL has a particular *chirality*, i.e., a rotational sense imposed by the orientation of the magnetic field; second, the position of the guiding center is not sharply defined, but submitted to a Heisenberg uncertainty relation—it is spread over a surface $2\pi l_B^2$ that can be viewed as the surface occupied by a quantum state in a particular LL. The total degeneracy N_B of each LL is therefore given by the total surface S divided by this minimal surface, $N_B = S/2\pi l_B^2 = SB/(\hbar/e)$, which is nothing other than the total flux threading the 2D system, in units of the flux quantum h/e . As a consequence of the fermionic nature of the electrons and Pauli's exclusion principle, the filling of the LLs is therefore determined by the filling factor

$$\nu = \frac{N_{\text{el}}}{N_B} = \frac{n_{\text{el}}}{n_B}, \quad (2)$$

in terms of the total number of electron $N_{\text{el}} = S n_{\text{el}}$.

The IQHE arises every time that an integer number of LLs is completely filled, i.e., at $\nu = j$. In this case, the Fermi level resides between the LLs $n-1$ and n , and the system is a bulk insulator. Strictly speaking, n should be an even integer due to the twofold spin degeneracy, but the latter is lifted either by the Zeeman effect or the formation of a ferromagnetic state due to exchange effects that

¹Since we are interested, here, in electrons of negative charge, the following expressions are those for particles with charge $-e$, in terms of the elementary charge e , which we set to be positive.

favor a full spin polarization (see section “Spin-valley quantum Hall ferromagnets”). The conductance is then governed by j chiral ballistic edge channels the chirality of which is imposed by the orientation of the magnetic field, while additional electrons (or holes) that occupy adjacent LLs, if the filling factor is not precisely an integer, do not contribute to the electric transport due to their localization by the bulk impurities. It is noteworthy to mention that this is a particular form of the bulk-edge correspondence that makes the IQHE a prototype of a topological insulator, where the bulk is insulating but the edges are necessarily conducting.

As already mentioned, the graphene is special because the band dispersion is not quadratic in the vicinity of the Fermi level. In charge-neutral (i.e., undoped) graphene, the Fermi level is situated at the two inequivalent points K and K' in the first Brillouin zone, where the valence band touches the conduction band with a dispersion that is linear in the wave vector. This has two consequences. First, the low-energy spectrum in the vicinity of the Fermi level is *twofold valley-degenerate*; second, the Bloch Hamiltonian must account for both conduction and valence bands on equal footing, via the 2×2 -matrix form

$$H(\mathbf{k}) = \hbar v_F \begin{pmatrix} 0 & (k_x - ik_y) \\ (k_x + ik_y) & 0 \end{pmatrix}. \quad (3)$$

This is precisely the 2D Dirac Hamiltonian of a massless particle in relativistic quantum mechanics, moving at the Fermi velocity v_F instead of the speed of light. Upon the same replacement of the wave vector by its gauge-invariant form as discussed above, $\hbar \mathbf{k} \rightarrow \mathbf{p} + e\mathbf{A}(\mathbf{r})$, to account for the magnetic field, one obtains the LL spectrum

$$E_n^G = \lambda \hbar \frac{v_F}{l_B} \sqrt{2n}, \quad (4)$$

where $\lambda = \pm$ denotes the two bands ($\lambda = +$ for the conduction and $\lambda = -$ for the valence band), and the ratio between the Fermi velocity and the magnetic length, v_F/l_B , plays the role of the cyclotron frequency here. It is clear from this spectrum that each LL in the conduction band has its counterpart in the valence band, apart from the $n = 0$ LL that is fixed at zero energy.

Similarly to LLs in non-relativistic 2D electron systems with a quadratic band dispersion, the LLs of graphene are highly degenerate, and the number of states per LL is again given by the number of flux quanta threading the 2D surface. Indeed, the argument invoked above—that the center of the cyclotron motion is a constant of motion and that there exists a minimal surface occupied by any quantum state in a LL—does not require a particular form of the electronic bands, but it is generally valid, regardless of the precise form of the LL spectrum. However, the internal degrees of freedom are not the same. While in a conventional 2D electron system, one is simply confronted with the twofold spin degeneracy, in the absence of the Zeeman effect, graphene LLs are fourfold degenerate. In addition to the usual spin, one has a twofold valley degeneracy as a consequence of the above-mentioned two inequivalent points K and K' where the Fermi level crosses the electronic bands. The electrons are therefore formally described within an $SU(4)$ symmetry, which arises as a consequence of the possibility to make a quantum-mechanical superposition of the orbital wave functions of each for the four spin-valley combinations $|\uparrow, K\rangle$, $|\uparrow, K'\rangle$, $|\downarrow, K\rangle$, and $|\downarrow, K'\rangle$, where $s = \uparrow, \downarrow$ denotes the spin orientation. This particular $SU(4)$ symmetry, which is respected to great extent in graphene LLs due to the smallness of the Zeeman effect and other valley-degeneracy lifting terms (Goerbig, 2011), turns out to be of great relevance for the understanding not only of the FQHE in graphene, but also for the formation of exotic quantum-Hall ferromagnetic phases that are discussed in the following sections. If one discards these phases for the moment, one therefore expects an IQHE in graphene at filling factors that are spaced in units of four due to the fourfold spin-valley degeneracy. This has indeed been observed experimentally (Novoselov et al., 2005; Zhang et al., 2005), but moreover the filling-factor series at which the IQHE occurs has an offset of two as compared to the IQHE in conventional 2D electron systems. This offset can be understood in the following manner. In contrast to non-relativistic systems, where the absence of any charge carriers at $\nu = 0$ leads to a completely empty lowest LL, charge neutrality in graphene ($\nu = 0$) means that the zero-energy LL $n = 0$ is globally half-filled; there are as many electrons as holes that occupy the $n = 0$ LL. Therefore, the Fermi level is situated inside this LL and not in the energy gap between two adjacent LLs, as it is required for the occurrence of the IQHE. The latter situation arises only at $\nu = 2$, when the $n = 0$ LL is completely filled, or at $\nu = -2$ when it is empty. In graphene, the IQHE thus occurs at the filling factors

$$\nu = \pm(4n + 2) = \pm 2(2n + 1), \quad (5)$$

as it has been demonstrated experimentally (Novoselov et al., 2005; Zhang et al., 2005). This particular filling-factor sequence of the IQHE is a fingerprint of the relativistic nature of the electrons in graphene.

Electrons in a single Landau level

In the preceding section, it was discussed that the IQHE arises as a consequence of Landau quantization every time that the Fermi level resides in between two adjacent LLs. As a consequence of the $SU(2)$ spin symmetry in conventional 2D electron system, this is the case for $\nu = 2(n + 1)$, while the combination of (i) the relativistic nature of graphene electrons and (ii) their $SU(4)$ spin-valley degeneracy yields an IQHE at $\nu = \pm 2(2n + 1)$ in graphene. In the present section, we discuss which of these two particularities are inherited by the FQHE in graphene. Because the FQHE phases occur at fractionally filled LLs, one needs to restrict the electronic dynamics to a single LL: the low-energy excitations are now those inside the same LL whereas excitations across LLs can be treated as belonging to high-energy degrees of freedom of a characteristic energy given by the LL separation, i.e., the energy scale $\hbar\omega_C$ in

Fig. 2 Sketch of the low-energy model of electrons restricted to a single LL. The Fermi level is situated in the partially filled LL (black circles represent the occupied states), while the LLs below are completely filled (gray circles) and those above completely empty. Excitations across LLs (red arrows) are associated with an energy given by the LL separation $\hbar\omega_C$ and belong to the neglected high-energy degrees of freedom, while excitations in the same LL are governed by the Coulomb interaction V_C .

conventional 2D electron systems or $\hbar v_F/l_B$ in graphene. This is depicted in Fig. 2. For the low-energy electronic excitations inside a single LL, the kinetic energy is therefore quenched, and the physical properties are governed by the Coulomb repulsion between the electrons.²

The low-energy electronic model finally appeals to the Coulomb interaction between the electronic densities $\rho_n(\mathbf{r})$ restricted to a single LL n ,

$$H = \frac{1}{2} \int d^2r d^2r' \rho_n(\mathbf{r}) V(\mathbf{r} - \mathbf{r}') \rho_n(\mathbf{r}'), \quad (6)$$

where $V(\mathbf{r}) = e^2/\epsilon |\mathbf{r}|$ is the usual Coulomb potential, which may eventually be screened due to a dielectric environment or the presence of gates. These screening properties are generically taken into account by the dielectric function ϵ . Let us now turn our attention in more detail to the LL-restricted densities $\rho_n(\mathbf{r})$, which are more conveniently described in reciprocal space, i.e., by Fourier transformation,

$$\rho_n(\mathbf{q}) = \int d^2r \rho_n(\mathbf{r}) e^{-i\mathbf{q} \cdot \mathbf{r}} = \left\langle \sum_j e^{-i\mathbf{q} \cdot \mathbf{r}_j} \right\rangle_n = F_n(\mathbf{q}) \bar{\rho}(\mathbf{q}), \quad (7)$$

where $\langle \dots \rangle_n$ indicates the restriction to the n -th LL, of the Fourier components $\sum_j \exp(-i\mathbf{q} \cdot \mathbf{r}_j)$ of the density operator in terms of the position operator $\mathbf{r}_j$ of the j -th particle. From a quantum-mechanical point of view, this restriction is necessary because the position operator has components in all LLs, and restricting the electron dynamics to a single LL amounts to replacing the position operator precisely by that of the guiding center $\mathbf{R}_j$. As mentioned above, $\mathbf{R}_j$ is a constant of motion and thus commutes with the kinetic Hamiltonian that gives rise to the LLs. The projected density operator in Eq. (7) is thus implicitly defined as $\bar{\rho}(\mathbf{q}) = \sum_j \exp(-i\mathbf{q} \cdot \mathbf{R}_j)$. The form factor $F_n(\mathbf{q})$ on the right-hand side of the expression (7) takes into account the LL wave functions that are system-dependent. In the case of the conventional 2D electron gaz (e.g., in GaAs heterostructures), it is given in terms of Laguerre polynomials,

$$F_n^{\text{2DEG}}(\mathbf{q}) = L_n \left(\frac{q^2 l_B^2}{2} \right) e^{-q^2 l_B^2 / 4}, \quad (8)$$

while in graphene one needs to distinguish the $n = 0$ LL from the other levels,

$$F_{n=0}^G(\mathbf{q}) = e^{-q^2 l_B^2 / 4} \text{ and } F_{n \neq 0}^G(\mathbf{q}) = \frac{1}{2} \left[L_{n-1} \left(\frac{q^2 l_B^2}{2} \right) + L_n \left(\frac{q^2 l_B^2}{2} \right) \right] e^{-q^2 l_B^2 / 4}. \quad (9)$$

The form factors can be absorbed into an *effective interaction potential*

$$v_n(\mathbf{q}) = \frac{2\pi e^2}{\epsilon(\mathbf{q})|\mathbf{q}|} [F_n(\mathbf{q})]^2, \quad (10)$$

so that the electronic properties in a partially filled LL and thus the correlated phases responsible for the FQHE are governed by the model

$$H = \frac{1}{2} \sum_{\mathbf{q}} v_n(\mathbf{q}) \bar{\rho}(-\mathbf{q}) \bar{\rho}(\mathbf{q}). \quad (11)$$

While this is a theoretical model that one would also start with for the description of electronic correlations in flat bands, the Hamiltonian (11) is quite special as a consequence of the magnetic field. Indeed, the magnetic field is still present via the guiding-center operators, which enter into the expressions for the restricted density operators, and its quantum-mechanical

²There is a second natural energy scale that is set by the inevitable impurities in the 2D systems. However, since the FQHE and other remarkable phases occur only in high-quality samples, the Coulomb repulsion is the leading energy scale and impurities should be treated perturbatively as a subordinate effect. Their main role is then to localize the quasiparticles of the FQHE liquid and thus to fix the Hall resistance over a certain filling-factor range, whence the appearance of the Hall plateau.

commutation relations impose a particular chirality on the electronic states. They induce highly unusual commutation relations for the density operators (Girvin et al., 1986)

$$[\bar{\rho}(\mathbf{q}), \bar{\rho}(\mathbf{q}')] = 2i \operatorname{sgn}(B) \sin\left(\frac{\mathbf{q} \wedge \mathbf{q}' l_B^2}{2}\right) \bar{\rho}(\mathbf{q} + \mathbf{q}'), \quad (12)$$

where $\mathbf{q} \wedge \mathbf{q}' = q_x q'_y - q_y q'_x$ is the 2D vector product. The chirality is hidden in the expression on the right-hand side of Eq. (12), the sign of which is determined by the orientation of the magnetic field in the z -direction perpendicular to the 2D plane. This chirality is inherited from that of the guiding-center components, as discussed in the previous section.

To summarize this theoretical section on the basic model encoding the exotic physical properties of the FQHE, the correlated phases require

- flat degenerate levels (or bands), that are the LLs here, i.e., a quenched kinetic energy;
- repulsive interactions between the electronic density components inside this level, such as it is described by the Hamiltonians (6) and (11);
- a chirality of the quantum states that is encoded, here, in the commutation relation between the components of the guiding-center operator, $[X, Y] = i l_B^2 \operatorname{sgn}(B)$, and that yields a non-commutativity (12) to the Fourier components of the projected density operators;
- the precise form of the LL spectrum is irrelevant for the structure of this low-energy model, but it has an indirect effect via the effective interaction potential, which accounts for the LL wave functions.

This summary is noteworthy since recent theoretical and numerical studies have shown that the FQHE phases are not restricted to partially filled LLs in 2D systems in a strong magnetic field, but they can be found also in partially filled flat electronic 2D bands with a non-zero Chern number (Regnault and Bernevig, 2011), in which case one speaks of *fractional Chern insulators*. Indeed, in this case the low-energy model for interacting electrons in a flat band has the same structure as that of 2D electrons in a single LL if one uses an average Berry curvature that is homogeneous in reciprocal space over the first Brillouin zone (Parameswaran et al., 2012; Goerbig, 2011). Finally, one should retain from this discussion that the difference between the FQHE in conventional 2D electron systems and that in graphene stems not from the particular form of the LLs—be they relativistic or non-relativistic—but from (i) the different wave functions that yield slightly different effective interaction potentials and (ii) from the internal degrees of freedom, which turn out to be fourfold in the case of graphene because of the fourfold spin-valley degeneracy of its LLs. In contrast to the IQHE, there is thus nothing such as a relativistic version of the FQHE in graphene.³ The (effective) Coulomb interaction in Eq. (10) respects this SU(4) symmetry; symmetry-breaking terms are suppressed algebraically in a/l_B , where $a = 0.14$ nm is the characteristic distance between nearest-neighbor carbon atoms in the graphene lattice, and the magnetic length is much larger at physically accessible magnetic fields, $l_B \simeq 24$ nm/ $\sqrt{B[\text{T}]}$.

Correlated electronic phases in partially filled Landau levels in graphene

Based on the model presented in the previous section, we now describe the main electronic phases encountered in partially filled Landau levels. Quite generally, one might already mention that due to the flatness of the Landau levels, spin- and valley-polarized states are favored in order to minimize the exchange energy. This is reminiscent of the usual itinerant ferromagnetism, with the notable difference that in the case of LLs there is no cost in kinetic energy to fully polarize the electrons. This picture turns out to be the correct one in the description of quantum-Hall ferromagnetic (QHFM) states at integer filling factors other than the graphene sequence $\nu = \pm 2(2n + 1)$, and, because of the conceptually simpler description, we present the particular physical properties of these states in section “Spin-valley quantum Hall ferromagnets” before the FQHE. However, this picture is more questionable in the theoretical description of the FQHE. As we discuss below, the *exchange energy* might be outcast in several situations by the *correlation energy*, which is intrinsically built into the trial wave functions such as the multi-component Halperin or Jain wave functions. In first exact-diagonalization studies that considered a completely polarized spin but a free valley polarization and that took into account the particular graphene LL form factors (9), the FQHE state at $\nu = 1/3-2$ turned out to be fully polarized while that at $\nu = 2/5-2$ is a valley singlet (Apalkov and Chakraborty, 2006). The strong variation of the spin-valley polarization of the various FQHE states has later been corroborated in theoretical studies that take into account the fourfold spin-valley degeneracy either in a four-component CF approach (Tóke and Jain, 2007) or in an approach that appeals to four-component generalizations of the Halperin wave function (Goerbig and Regnault, 2007).

From an experimental point of view, it is more difficult to obtain information about the spin-valley polarization of the various states. Signatures for the SU(4) nature of the $1/3$ -family of the FQHE have been obtained in transport measurements of graphene on h-BN (Dean et al., 2011) and later in compressibility measurements of the CF series at $\nu = p/(2sp + 1)$ in different subbranches of the $n = 0$ LL in suspended graphene (Feldman et al., 2012). However, they are not based on a direct measurement of the spin or valley polarization but on a relative comparison between the gaps and visibilities of the various states.

³Notice that a relativistic description has been adopted with great success in the description of a half-filled LL that accounts naturally for the particle-hole symmetry manifest at this filling (Son, 2015). However, this particular description is by no means inherited from the original LLs since it has been used also in the context of conventional 2D quantum Hall systems, such as in GaAs heterostructures.

Spin-valley quantum Hall ferromagnets

The most straight-forward manifestation of the Coulomb repulsion is certainly the formation of QHFM states at integer fillings other than the characteristic IQHE series $\nu = \pm 2(2n + 1)$ in graphene. This is easily understood in analogy with ferromagnetism of itinerant electrons: in order to minimize the Coulomb repulsion, the orbital part of the overall N -electron wave function should be as antisymmetric as possible such that the probability to find two electrons at the same position is decreased. Because of the fermionic global antisymmetry of the electronic wave function, the spin-valley part must therefore be symmetric, i.e., maximally spin-valley polarized, that is precisely the hallmark of an SU(4) ferromagnetic state. Because of the flatness of the LL, this polarization is not accompanied by a cost in kinetic energy as for itinerant electrons in dispersive energy bands.

Let us illustrate the particular SU(4) QHFM states in the LL $n = 0$. One needs to distinguish two cases, (i) $\nu = -1$, which is related by particle-hole symmetry to the case $\nu = +1$, and (ii) $\nu = 0$ at charge neutrality. At $\nu = -1$, one of the spin-valley components $\alpha = |\uparrow, K\rangle, |\uparrow, K'\rangle, |\downarrow, K\rangle, |\downarrow, K'\rangle$ is completely filled, and the associated wave function reads

$$\psi_{\nu=-1} = \prod_{k_x < l_x}^{N_B} (z_{k_x} - z_{l_x}) \exp \left(- \sum_{j_x=1}^{N_B} |z_{j_x}|^2 / 4l_B^2 \right), \quad (13)$$

in terms of the complex position $z_{j_x} = x_{j_x} - iy_{j_x}$ of the j_x -th electron in the component α . Because of the SU(4) symmetry of the Coulomb interaction, there is no spin-valley component favored over another one, and α could even represent an arbitrary quantum-mechanical superposition of the four components. Notice, however, that the SU(4) symmetry is eventually broken by interactions at the lattice scale (Alicia and Fisher, 2006; Herbut, 2007; Kharitonov, 2012), electron-phonon interactions (Fuchs and Lederer, 2007; Nomura et al., 2009) or simply the Zeeman effect. Generally, these effects are associated with energy scales that are one or two orders of magnitude smaller than the leading SU(4)-symmetric Coulomb repulsion (Goerbig, 2011), and we therefore consider the symmetric case first. Similarly, the QHFM wave function at charge neutrality ($\nu = 0$) can be written as

$$\psi_{\nu=0} = \prod_{k_x < l_x}^{N_B} (z_{k_x} - z_{l_x}) \prod_{k_\beta < l_\beta}^{N_B} (z_{k_\beta} - z_{l_\beta}) \exp \left(- \sum_{j_x=1}^{N_B} |z_{j_x}|^2 / 4l_B^2 - \sum_{j_\beta=1}^{N_B} |z_{j_\beta}|^2 / 4l_B^2 \right), \quad (14)$$

i.e., the two components α and β are now completely filled. As in the case $\nu = -1$, one may freely choose α and β among the four components, including quantum-mechanical superpositions of them, as long as the components α and β are orthogonal to one another.

Both at $\nu = -1$ and $\nu = 0$, the large variety of SU(4) polarizations is eventually fixed by the above-mentioned subleading symmetry-breaking terms, which are easily taken into account within a non-linear sigma model. In the conceptually simpler case $\nu = -1$, the energy due to these anisotropic terms can be written as (Nomura et al., 2009; Lian and Goerbig, 2017)

$$E_A = \frac{N_B}{2} \left[u_z M_{P_z}^2 + u_\perp (M_{P_x}^2 + M_{P_y}^2) \right] - N_B \Delta_Z M_{S_z}, \quad (15)$$

where $M_{S_\mu} = \langle F | \sigma_\mu | F \rangle$ is the spin polarization of a general superposition $|F\rangle$ of the four different spin-valley components, in terms of the Pauli matrices σ_μ acting on the spin components of $|F\rangle$. Similarly, $M_{P_\mu} = \langle F | \tau_\mu | F \rangle$ is the valley polarization of $|F\rangle$ in terms of the Pauli matrices τ_μ that now act on the valley components of $|F\rangle$. The usual Zeeman effect is taken into account by the energy scale Δ_Z , while u_z and $u_\perp$ act on the valley components. As mentioned above, they account for either lattice-scale interactions (Alicia and Fisher, 2006; Herbut, 2007; Kharitonov, 2012) or electron-phonon coupling.

The resulting phase diagram is shown in Fig. 3a, as a function of u_z/Δ_Z and $u_\perp/\Delta_Z$. It can be understood in the following manner. Apart from the *canted antiferromagnetic* (CAF) and the *antiferromagnetic* (AFI) phases, the spin and valley polarizations are fully decoupled. Indeed, at $\nu = -1$, the system can be both fully spin- and fully valley-polarized, e.g., if all electrons occupy the state $|F\rangle = |\uparrow, K\rangle$. This is the case in the *charge-density-wave* (CDW) phase that is stabilized if $u_z < u_\perp < \Delta_Z$. The particular sublattice occupation, where only one sublattice is occupied, is a consequence of the particular nature of the one-particle wave functions in the

Fig. 3 Phase diagram for the QHFM phases at (a) $\nu = -1$ and (b) $\nu = 0$, as a function of the parameters u_z/Δ_Z and $u_\perp/\Delta_Z$. (a) At $\nu = -1$, the CDW and KD phases come along with a full spin polarization since the spin and valley degrees of freedom are decoupled. On the contrary, the AFI and CAF phases show spin-valley entanglement. The sketches indicate the lattice-resolved spin densities in the different phases. (b) At $\nu = 0$ the full valley polarization of the CDW and KD phases are spin-unpolarized, and the F phase with full spin polarization is therefore distinct from the former two phases. The CAF phase shows spin-valley entanglement.

graphene $n = 0$ LL, where sublattice and valley are identical: electrons of the valley K have a non-zero wave function only on one sublattice, while electrons of the valley K' solely occupy the other sublattice. Similarly, for $u_{\perp} < u_z < \Delta_Z$, the valley polarization is preferentially in a superposition of the valleys K and K' , along with a full spin polarization in the z -direction. This superposition manifests itself in a particular lattice pattern in the form of a *kekulé distortion* (KD).

The phases CAF and AFI merit special attention. They are specific SU(4) ferromagnetic phases that have no counterpart in the usual SU(2) ferromagnetism since they are driven by an entanglement between the spin and valley degrees of freedom. Consider for example the AFI phase, which becomes antiferromagnetic in the limit of a vanishing Zeeman gap, $\Delta_Z \rightarrow 0$. From the above-mentioned perspective, it is perfectly admitted to construct an equal-weight superposition of the states $|\uparrow, K\rangle$ and $|\downarrow, K'\rangle$ of all electrons. In this case, the SU(4) QHFM consists only of spin- $\uparrow$ electron in the K valley, i.e., on one sublattice, while the other sublattice (associated with the valley K') only hosts spin- $\downarrow$ electrons. This would commonly be referred to as an *antiferromagnetic* state, but one must insist that it is an SU(4) *ferromagnetic* phase which can be transformed into one of the other QHFM phases by a global SU(4) rotation. This state is favored at positive values of u_z and $u_{\perp}$, which prefer to have a vanishing valley polarization in all directions, as one may see from Eq. (15). As a matter of fact, due to the spin-valley entanglement, a vanishing valley polarization comes along with a vanishing spin polarization (Douçot et al., 2008). However, a fully vanishing spin polarization can be achieved only in the limit of zero Zeeman effect, which otherwise prefers a non-zero value of the spin polarization in the z -direction, whence the term *antiferromagnetic*. Similarly the CAF phase has a net spin polarization out of plane to account for the Zeeman effect, but an inplane antiferromagnetic pattern.

The phase diagram at $\nu = 0$ has similar phases (Kharitonov, 2012), but one needs to take into account the fact that now two components are fully occupied by electrons, as stipulated by the wave function (14). In this case, one cannot polarize fully both the spin and the valley, i.e., one now needs to make a distinction between the spin-polarized *ferromagnetic* (F) phase and the valley-polarized phases CDW and KD. The F phase comes along with a zero valley polarization while the CDW and KD phases are accompanied by a vanishing spin polarization. Again, it is possible to profit from spin-valley entanglement via special superpositions, such as in the CAF phase. The phase diagram (Kharitonov, 2012; Atteia et al., 2021) is shown in Fig. 3b for the same parameters u_z , $u_{\perp}$ and Δ_Z . The precise values of these parameters are yet unknown and they are likely to depend on the concrete physical system, e.g., the (dielectric) environment of the graphene sheet or its amount of disorder. Recent scanning-tunneling-spectroscopic measurements have found evidence for all four phases at $\nu = 0$ (Liu et al., 2022; Coissard et al., 2022), for graphene on different substrates.

Magnons

As a consequence of the spontaneously broken SU(4) symmetry in the formation of a QHFM, special low-energy collective excitations, called *Goldstone modes*, occur if one perturbs slightly the ground states. They are nothing other than generalized spin waves (magnons) that happen again to be special in graphene as a consequence of the relatively large SU(4) symmetry. In addition to the usual spin waves one has valley waves and mixed spin-valley magnons. This can be seen most easily again at $\nu = -1$, for which the situation is depicted in Fig. 4a. Indeed, a simple counting of the possible modes indicates that there are three magnon branches. In the case of an SU(4)-symmetric interaction all three branches have the same dispersion

$$E_q = 2 \sum_{\mathbf{k}} \nu_n(\mathbf{k}) \sin^2 \left(\frac{\mathbf{q} \wedge \mathbf{k} l_B^2}{2} \right), \quad (16)$$

in terms of the effective interaction (10) and the pair wave vector $\mathbf{q}$. Indeed, a magnon can be viewed as a superposition at a specific wave vector $\mathbf{q}$ of a hole in the component α , which is fully occupied in the QHFM state $|F\rangle$, and an electron in the originally empty component β . Since the superposition is charge-neutral, the pair wave vector $\mathbf{q} = \Delta \mathbf{R} \times \mathbf{e}_z / l_B^2$, which is related to the spatial separation $\Delta \mathbf{R} = \mathbf{R} - \mathbf{R}'$ between the guiding center of the electron $\mathbf{R}$ and that of the hole $\mathbf{R}'$ and the orientation of the magnetic field $\mathbf{e}_z = \mathbf{B}/|\mathbf{B}|$, remains a constant of motion even in the presence of a magnetic field, contrary to the wave vectors of the original (charged) constituents of the pair. In the central $n = 0$ LL, this yields the magnon dispersion (Kallin and Halperin, 1984; Yang et al., 2006; Doretto and Smith, 2007)

$$E_q = \sqrt{\frac{\pi}{2}} \frac{e^2}{\epsilon l_B} \left[1 - e^{-q^2 l_B^2 / 4} I_0 \left(\frac{q^2 l_B^2}{2} \right) \right], \quad (17)$$

in terms of the modified Bessel function $I_0(x)$. The two limits for small and large wave vectors are readily understood; at small wave vectors, one retrieves the usual quadratic

Fig. 4 Generic magnons at (a) $\nu = -1$ and (b) $\nu = 0$. The $n = 0$ LL hosts four spin-valley copies that are separated for illustration reasons while they remain degenerate in energy in the absence of explicit SU(4)-symmetry-breaking terms. At $\nu = -1$ (and its particle-hole-symmetric situation at $\nu = 1$) one of the spin-valley components is completely occupied and one obtains three magnon modes. At $\nu = 0$, two components are filled and one has four magnon modes.

$$E_{q \rightarrow 0} \simeq \frac{\rho_s}{2} q^2 l_B^2 \quad (18)$$

behavior of the Goldstone mode, in terms of the spin stiffness

$$\rho_s = \frac{1}{16\sqrt{2\pi}} \frac{e^2}{\epsilon l_B}, \quad (19)$$

while at large wave vectors, the dispersion saturates at twice the exchange gap $E_X = \sqrt{\pi/8} e^2 / \epsilon l_B$,

$$E_{ql_B \gg 1} \simeq \left[2\sqrt{\frac{\pi}{8}} - \frac{1}{ql_B^2} \right] \frac{e^2}{\epsilon l_B}. \quad (20)$$

Because the exchange gap E_X can be viewed as the energy to create a quasiparticle or a quasihole with a reversed spin, $2E_X$ is nothing other than the particle-hole dissociation energy, while at finite wave vectors with $ql_B > 1$ one needs to take into account the binding energy between the electron and the hole, which is given by the Coulomb energy $E_{\text{Coul}} = e^2/\epsilon |\Delta \mathbf{R}| = e^2/\epsilon ql_B^2$ in the second term of the dispersion relation.

Similarly to the QHFM ground states, the magnon spectrum becomes modified when the anisotropic terms (15) are taken into account. Because the degeneracy between the SU(4) QHFM states is lifted, the magnons depend on the precise form of the chosen state. Furthermore, the magnons become generally gapped, e.g., by the Zeeman term for the spin magnons and the terms u_z and $u_\perp$ for the valley magnons (Atteia and Goerbig, 2021). Most saliently, the magnon dispersion may even change its wave-vector dependence, e.g., in the KD phase. Indeed, in this phase the energy functional, even in the presence of the anisotropic terms, remains U(1)-symmetric, while this symmetry is spontaneously broken by the intervalley coherence in the KD phase. This yields a particular gapless magnon with a dispersion that is linear in the wave vector.

Finally, the above energy arguments remain valid at charge neutrality ($\nu = 0$), but the counting of the possible modes is changed. Because there are now two fully occupied spin-valley components (and two empty ones), one finds four possible magnon modes (Yang et al., 2006; Lambert and Côté, 2013; Wu et al., 2015; Wei et al., 2021). However, for an SU(4)-symmetric Coulomb interaction, the magnon dispersion is still given by Eq. (17), and again some of the different magnon modes become gapped in the presence of an explicit spin-valley anisotropy (15).

Skyrmions

A very particular type of topological objects are formed on top of the QHFM when additional charges are added to the ground states at $\nu = -1$ or $\nu = 0$. Consider an electron added to a perfect QHFM state at $\nu = 0$. Naturally, this additional electron must occupy a spin-valley component that was initially completely empty. From an exchange-energy point of view it is however much more favorable that this *spin-valley flip* does not only concern the additional electron, but the latter encourages electrons in its vicinity to do likewise such as to minimize the overall exchange energy. This is depicted in Fig. 5 for a generic situation at $\nu = 0$. The skyrmion is a texture that appeals to one of the two originally occupied spin-valley components (here $|F_2\rangle$) and one of the unoccupied ones (here $|C_2\rangle$). As in the QHFM ground state, these components can be any type of superposition of the original spin-valley components, but all states, the occupied ones $|F_1\rangle$ and $|F_2\rangle$ as well as the unoccupied ones $|C_1\rangle$ and $|C_2\rangle$, must be mutually orthogonal. While the QHFM ground state fixes the states $|F_1\rangle$ and $|F_2\rangle$, there is yet a certain choice for the spinor $|C_2\rangle$ that describes the spin-valley polarization at the skyrmion core. Indeed, the skyrmion can be generically described by the field

$$|Z(x + iy)\rangle = \frac{1}{\sqrt{1 + (x^2 + y^2)/|\lambda|^2}} \left(|C_2\rangle + \frac{x + iy}{\lambda} |F_2\rangle \right), \quad (21)$$

where $|\lambda|$ denotes the typical skyrmion size. As for the QHFM states, the lowest-energy skyrmion that is realized in the system depends on the SU(4)-symmetry-breaking terms (15), and both at $\nu = -1$ (Lian et al., 2016; Lian and Goerbig, 2017) and at $\nu = 0$ (Atteia et al., 2021), one finds a whole *skyrmion zoo* that is not presented here. However, it needs to be underlined that very recently there has been first spectroscopic evidence for the presence of skyrmions in graphene at $\nu = 0$ (Liu et al., 2022), in

Fig. 5 Generic skyrmion at $\nu = 0$. The sublevels $|F_1\rangle$ and $|F_2\rangle$ are occupied in the QHFM ground state. The skyrmion consists of an electron that is promoted from the spin-valley component $|F_2\rangle$ to the initially unoccupied component $|C_2\rangle$ at the skyrmion core $z = 0$. Slightly away from the core, the electrons are in a superposition of $|C_2\rangle$ and $|F_2\rangle$, the relative weight of which changes upon increase of $|z|$. The typical size $|\lambda|$ indicates the equal-weight superposition of the two components, while at $|z| \rightarrow \infty$ the superposition converges to the QHFM background $|F_2\rangle$. At all distances, $|F_1\rangle$ remains unchanged as well as the unoccupied spectator component $|C_1\rangle$.

scanning-tunneling spectroscopy. While the QHFM is likely to be a KD phase, the spin-valley pattern at the skyrmion core is reminiscent of the CAF phase. Both phases have a particular signature in the sublattice occupation that has been precisely measured in the experiment.

Fractional quantum Hall states

In order to describe the four-component FQHE in graphene, one may start with a four-component generalization of Halperin's wave function (Goerbig and Regnault, 2007),

$$\psi_{m_1, \dots, m_4; n_{\alpha\beta}} = \phi_{m_1, \dots, m_4}^L \phi_{n_{\alpha\beta}}^{\text{inter}} \exp \left(- \sum_{\alpha=1}^4 \sum_{j_z=1}^{N_\alpha} |z_{j_z}|^2 / 4l_B^2 \right), \quad (22)$$

where

$$\phi_{m_1, \dots, m_4}^L = \sum_{\alpha=1}^4 \sum_{k_z < l_z}^{N_\alpha} (z_{k_z} - z_{l_z})^{m_\alpha} \quad (23)$$

is the product of 4 Laughlin wave functions for each of the four components $\alpha, \beta = |\uparrow, K\rangle, |\uparrow, K'\rangle, |\downarrow, K\rangle, \text{ and } |\downarrow, K'\rangle$. In the absence of inter-component correlations, which are taken into account in the term

$$\phi_{n_{\alpha\beta}}^{\text{inter}} = \prod_{\alpha < \beta} \prod_{k_z}^{N_\alpha} \prod_{l_\beta}^{N_\beta} (z_{k_z} - z_{l_\beta})^{n_{\alpha\beta}}, \quad (24)$$

the exponents m_α are directly related to the component filling factors $\nu_\alpha = N_\alpha/N_B = 1/m_\alpha$, which enter the total filling factor

$$\nu = \sum_{\alpha} \nu_\alpha - 2, \quad (25)$$

in terms of the number of electrons per component N_α and the total number of electron N_{el} . The offset of 2 in the expression for the total filling factor is due to the fact that the $n = 0$ LL in graphene is completely empty (for $\nu_\alpha = 0$) at $\nu = -2$ because charge neutrality ($\nu = 0$) corresponds to a globally half-filled $n = 0$ LL, as mentioned in section "Landau levels and the integer quantum Hall effect in graphene". In general, however, the total filling factor for a four-component Halperin wave function depends not only on the exponents m_α but also on the inter-component correlations $n_{\alpha\beta}$, via the relation

$$1 = m_\alpha \nu_\alpha = \sum_{\beta \neq \alpha} n_{\alpha\beta} \nu_\beta. \quad (26)$$

Notice that the exponents m_α and $n_{\alpha\beta}$ induce correlations between the electrons. While the Pauli principle (i.e., the antisymmetry of the fermionic wave functions) only requires $m_\alpha = 1$ and does not constrain the inter-component correlations, the Halperin wave function (22) indicates that the electronic density of an electron of type α approaching another one of the same type is suppressed as $\sim r^{-2m_\alpha}$, and it is suppressed as $\sim r^{-2n_{\alpha\beta}}$ if an electron of type α approaches one of type β . These correlations are therefore globally favorable for the repulsive Coulomb interaction. However, not all combinations of exponents are eligible for physically relevant wave functions: if the inter-component correlations become stronger than the intra-component ones, the Halperin wave function no longer describes a spatially homogeneous electronic system but electrons in different components have a tendency to undergo a phase separation (de Gail et al., 2008). The four-component CF wave functions are more complex to write down, but the basic idea is to first rewrite a multi-component wave function of Halperin's type as a product

$$\psi = \phi_{\nu^*=1} \phi_{\text{SU}(4)}^{2s} \exp \left(- \sum_{\alpha=1}^4 \sum_{j_z=1}^{N_\alpha} |z_{j_z}|^2 / 4l_B^2 \right), \quad (27)$$

as a vortex part $\phi_{\text{SU}(4)}^{2s}$, and a wave function $\phi_{\nu^*=1}$ at a putative filling factor $\nu^* = 1$ for electrons of one, several or all components. In a second step, this wave function is then replaced by one for $\nu^* = p$ LLs that are called CF LLs (Töke and Jain, 2007). Since this wave function has non-analytical components, i.e., components in LLs other than $n = 0$, the new wave function needs to be ultimately projected into this LL.

The 1/3-family of fractional states in graphene

The generalized Halperin wave functions (22) may be used as a first approach to understand the particular form of the 1/3-family of fractional states, which has been observed in graphene on a h-BN substrate and that has been interpreted as a manifestation of the particular SU(4) symmetry of the FQHE (Dean et al., 2011). Indeed, if the fourfold spin-valley degeneracy were lifted by external perturbations such as the Zeeman effect, which favors a particular spin orientation, all four subbranches of the LLs would be well separated in energy. In this case, one may argue that the electrons in each of the subbranches form correlated states independently of the other (completely filled or completely empty) subbranches. The latter would be electronically inert similarly to the other LLs

that are remote in energy from the partially filled one, as we have discussed in section “Electrons in a single Landau level” where we constructed the low-energy model of electrons restricted to a single LL. In this case, one would expect to observe all spin-valley copies of the $1/3$ Laughlin state at $\nu = \pm 5/3, \pm 4/3, \pm 2/3, \pm 1/3$ in the $n = 0$ LL. However, this was not observed in the experiment (Dean et al., 2011), where the $\pm 5/3$ -states were almost absent in the measurement. In later experiments, at larger magnetic fields, the latter states became more pronounced (Polshyn et al., 2018), in line with the intuitive expectations that at higher magnetic field the subbranches are better separated in energy (due to a $\propto B$ scaling with the magnetic field, in contrast to the expected $\sqrt{B}$ -scaling of the Coulomb interaction scale $e^2/\epsilon l_B$) such that a one-component treatment in terms of Laughlin wave functions becomes more reliable.

In order to describe the $-5/3$ -state (and its particle-hole symmetric one at $\nu = +5/3$), one can use the Halperin wave function (22), in which one sets all exponents $\mu_\alpha = n_{\alpha\beta} = 3$. In this case, one may interpret the state as an overall Laughlin wave function that is built up from all electrons regardless of the spin-valley components they occupy. In spite of its similarity with the usual one-component Laughlin state, one needs to emphasize that it is an intrinsic multi-component state with an internal $SU(4)$ spin-valley symmetry, which allows one to distribute the electrons freely over the different spin-valley components. This freedom has consequences in the excitation spectrum in the form of generalized spin waves, similarly to the QHFM states at $\nu = \pm 1$ (see section “Spin-valley quantum Hall ferromagnets”): there are altogether three modes, a spin magnon, a valley magnon and a mixed spin-valley mode, while the usual one-component Laughlin wave function would not have such excitations. The presence of these modes is likely to be at the origin of the reduced robustness of the $\pm 5/3$ states as compared to the other ones of the $1/3$ family.

The states at $\pm 1/3$ can also be understood in terms of the generalized Halperin wave functions (Papić et al., 2010). For illustration, consider a prominent Zeeman effect that favors a spin polarization over a valley polarization.⁴ In this case, we have the exponents $m_\alpha = 1$ for $\alpha = |\uparrow, K\rangle$ and $|\uparrow, K'\rangle$, while we have $m_\alpha = 3$ for $\alpha = |\downarrow, K\rangle$ and $|\downarrow, K'\rangle$. Furthermore, there are no correlations between $|\uparrow, K\rangle$ and $|\uparrow, K'\rangle$ such that the corresponding exponent is $n_{12} = 0$, while it is $n_{34} = 3$ for the correlations between $|\downarrow, K\rangle$ and $|\downarrow, K'\rangle$. Finally, there are no correlations between states of different spin orientation, $n_{13} = n_{14} = n_{23} = n_{24} = 0$. Similarly to the $\pm 5/3$ -states, this state has a residual symmetry in the $s = \downarrow$ -spin branch since one can freely distribute the electrons of this spin orientation over the two valleys, i.e., one is confronted with a residual $SU(2)$ symmetry that is spontaneously broken by the formation of the state and that supports thus a valley magnon. In addition to the number of generalized spin waves, there is an important difference between the Halperin states at $\nu = \pm 5/3$ and $\nu = \pm 1/3$: while the former is an eigenstate of the $SU(4)$ -symmetric Hamiltonian, the latter is not. It therefore requires an explicit spin-valley $SU(4)$ symmetry breaking, e.g., in the form of the above-mentioned Zeeman term Δ_Z , to stabilize this state. However, a term as small as $\Delta_Z/(e^2/\epsilon l_B) \simeq 0.01$ is sufficient to stabilize the state (Papić et al., 2010). Because $e^2/\epsilon l_B \simeq 109\sqrt{B[\text{T}]} \text{ K}$ for graphene on h-BN and $\Delta_Z \simeq 1.2B[\text{T}] \text{ K}$, this condition is fulfilled for fields as small as $B \sim 1 \text{ T}$, below the field values where the $1/3$ -states have been observed experimentally (Dean et al., 2011; Polshyn et al., 2018).

While numerical studies are less conclusive about their relevance at $\nu = \pm 2/3$ and $\pm 4/3$ (Wu et al., 2015; Le and Jolicoeur, 2022), Halperin wave functions may also be constructed for these filling factors, e.g., at $\nu = \pm 2/3$ with $m_1 = 1, m_2 = m_3 = m_4 = 3, n_{1\beta} = 0$ and $n_{\alpha\beta} = 3$ otherwise, which amounts to having one spin-valley subbranch completely filled, while the electrons in the other three subbranches form a Laughlin state with an $SU(3)$ symmetry. As for the $\pm 1/3$ -states, these states are not eigenstates of the $SU(4)$ -symmetric Coulomb interaction and therefore require a (small) spin-valley degeneracy lifting. Similarly, the $\nu = \pm 4/3$ states may, in a first step, be approached in terms of a Laughlin state composed of electrons (or holes) in a single spin-valley subbranch, $m_1 = 3$, while the other intra-component exponents are $m_\alpha = 1$, and there are no inter-component correlations, i.e., $n_{\alpha\beta} = 0$. From this perspective, the $\nu = \pm 4/3$ states are those that are closest to the one-component Laughlin states.

However, it is noteworthy to mention that there are other candidate states for $\nu = \pm 4/3$, and it is unlikely that the ground state be described in terms of these Halperin wave functions. Indeed, exact-diagonalization studies at $\nu = 2/3 - 2 = -4/3$ in graphene have shown that the state is a singlet in one of the channels (spin or valley) and fully polarized in the other one (Apalkov and Chakraborty, 2006; Töke and Jain, 2007; Goerbig and Regnault, 2007), and the spectra show magnon-type modes. Notice that, due to the large number of components, one may construct other Halperin wave functions for this filling factor, as for example a state with $m_\alpha = 3$ and $n_{\alpha\beta} = 1$, or else one with $m_\alpha = 3, n_{\alpha\beta} = n_{13} = n_{24} = 3$ for the correlations inside each valley and $n_{12} = n_{34} = n_{14} = n_{23} = 0$, i.e., no correlations for electrons in different valleys. While the latter trial state supports the numerically found magnon mode and has the correct ground-state degeneracy, there are no such modes in the former state in which the number of electrons is fixed in all components. Finally, one needs to emphasize that the different states are in competition with one another and that explicit subordinate spin-valley symmetry-breaking terms become relevant for the choice between these states, as it has just recently been shown in exact-diagonalization studies on the $1/3$ -family in graphene (Le and Jolicoeur, 2022), and in some cases trial states are required to be constructed beyond the Halperin or multi-component CF states (Wu et al., 2015).

The particularity of the CF series $p/(2sp + 1)$ in graphene

The discussion of the $1/3$ -FQHE states in graphene has shown to what extent the spin-valley degrees of freedom are relevant in understanding the effect. While one might think, in view of these results, that generally the system chooses a maximal spin-valley polarization compatible with the total filling factor, numerical studies of the CF series at $\nu = p/(2sp + 1) - 2$ have shown that the situation is more involved (Töke and Jain, 2007). From an electronic point of view, one may always find a CF wave function with complete spin-valley polarization for these filling factors, in which the CFs occupy p CF LLs (Jain, 1989), as mentioned in the

⁴The argument does not depend on this choice, however, and one may exchange spin and valley or any two components.

introduction. This, however, does not seem to be the scenario chosen by Nature. Instead, at $p = 2$ ($\nu = 2/5 - 2$), the electrons prefer to occupy another spin-valley branch instead of filling a second CF LL. This situation may either be described within an SU(4) spin-valley generalization of Jain's CF wave functions (Tóke and Jain, 2007) or in terms of the generalized Halperin wave function (22). It needs to be emphasized that both descriptions are equivalent for $p = 1, \dots, 4$. Consider the situation of a small Zeeman effect that favors a spin over a valley polarization. In this case, the state at $\nu = 2/5 - 2$ may be described by the wave function (22) with $m_x = 3$, $n_{x\beta} = n_{13} = n_{24} = 3$ for all inter-component correlations inside each valley and $n_{x\beta} = n_{12} = n_{34} = n_{14} = n_{23} = 2$. This state is a valley singlet, but the spin can be oriented freely for electrons inside each valley, i.e., the state has a residual SU(2) $\times$ SU(2) symmetry, and there are two spin-wave modes, one in each of the valleys.

A particularly interesting situation arises at $\nu = 4/9 - 2$, where all four components are filled such that the state is an SU(4) singlet with no magnon modes. This situation can be described in terms of the generalized Halperin wave function (22) with $m_x = 3$ and $n_{x\beta} = 2$ for all inter-component correlations, and numerical calculations show that this unpolarized state is indeed favored energetically over a completely polarized CF state (Tóke and Jain, 2007).

It is important to emphasize that such a completely unpolarized state or states with only partial polarization occur in this filling factor range of $-2 < \nu < -1$ (and by particle-hole symmetry in $1 < \nu < 2$). This is not in line with common expectations from the often used single-particle picture, where one is tempted to successively populate the different spin-valley branches separated in energy by Zeeman-type terms. As mentioned above, these terms are much smaller than the leading Coulomb interaction scale, and it is the latter that needs to be considered first. Also the picture of an exchange-driven maximal spin-valley polarization needs to be taken with care. While this picture is applicable at integer fillings such as $\nu = 0$ and ± 1 (and integer fillings different from the graphene IQHE series $\nu = \pm 2(2n + 1)$), where the exchange energy generates the QHFM states, the numerical studies of the CF series $p/(2sp + 1)$ in graphene indicate that the special correlation energy built in the FQHE wave functions generally outcasts the exchange energy and thus gives rise to an unexpected non-monotonic behavior of the spin-valley polarization if only the SU(4)-symmetric Coulomb repulsion is taken into account. However, as it has already been mentioned in the discussion of the 1/3-family, the precise nature of the CF states realized in a typical experimental situation may sensitively depend on the explicit symmetry-breaking terms. The energies of the different—polarized or unpolarized—trial states may be extremely close so that the latter subordinate terms are decisive in the choice of a particular type of states even if they are not the relevant scale in the formation of these states (Abanin et al., 2013; Le and Jolicœur, 2022).

Even-denominator states

A particular FQHE state is the even-denominator state observed at $\nu = 5/2$ and $7/2$ in 2D quantum-Hall systems in GaAs heterostructures (Willett et al., 1987). From an experimental point of view, it seems settled now that they are spin-polarized (Dean et al., 2008), as expected for the so-called Pfaffian state proposed by Moore and Read (Moore and Read, 1991). These states, however, observed in the $n = 1$ LL require a particular form of the effective interaction potential that is in line with that (10) for $n = 1$ in the usual 2D electron system.⁵ Right from the beginning of graphene research, it was realized that the particular form of the effective interaction potential (10), if the appropriate form factors are taken into account, does not allow for the stabilization of the Moore-Read Pfaffian state (Goerbig et al., 2006). However, it is possible to construct a multicomponent Halperin wave function also for this filling factor, e.g., with $m_x = 3$ and again $n_{x\beta} = n_{13} = n_{24} = 3$ for all intercomponent exponents inside each valley and $n_{x\beta} = n_{12} = n_{34} = n_{14} = n_{23} = 1$. Alternatively, if a valley-degeneracy lifting outcasts the Zeeman effect, one may exchange the role of the spin and valley indices. Recent capacitance measurements have shown that even-denominator states at $\nu = \pm 1/2, \pm 1/4$ can indeed be stabilized in the vicinity of a transition between two different spin-valley orders (Zibrov et al., 2018), which gives credit to the multi-component interpretation of the effect (Narayanan et al., 2018).

Electron crystals

While the FQHE states are certainly the most interesting correlated phases, due to their exotic quasiparticle excitations, they are, along with the QHFM phases, not the only correlated electronic phases that one encounters in partially filled LLs. Indeed, right after the discovery of the IQHE in the 1980s, some researchers proposed a Wigner crystal to be the ground state in partially filled LLs, in order to minimize the repulsive Coulomb potential. This classical state is indeed realized at low filling factors, in which case the magnetic length becomes much smaller than the average electronic spacing so that quantum-mechanical effects due to the electronic wave-function overlap can be neglected. From an experimental point of view, it is nevertheless difficult to identify an electronic solid in conventional transport measurements: the electronic crystals are collectively pinned by the underlying impurities and therefore yield an insulating response in the same manner as an individual electronic localization does.

From a theoretical point of view, electronic crystals become most interesting in higher LLs, where one does not only encounter the Wigner crystal but also more exotic bubble crystals, in which a lattice site is occupied by more than one electron, or stripe crystals. The phases have been theoretically predicted to arise in higher LLs in conventional GaAs heterostructures (Fogler et al., 1996; Moessner and Chalker, 1996), where e.g., the stripe crystals yield a highly anisotropic electronic transport in the LLs $n = 2$ (Lilly et al., 1999; Du et al., 1999). One of the most salient features of electronic crystals in higher LLs is the so-called reentrant IQHE, which was discovered in GaAs heterostructures (Cooper et al., 1999; Eisenstein et al., 2002). The effect consists of a non-monotonic behavior of the Hall resistance, in which a plateau corresponding to a FQHE is flanked by two plateaus at an

⁵From a technical point of view, this can be shown within an expansion of the effective interaction potential in Haldane's pseudopotentials (Haldane, 1983).

Fig. 6 Reentrant IQHE in graphene in the $n = 2$ LL. The non-monotonic behavior of the Hall conductance (red curve) as a function of the gate-voltage-induced electronic density is clearly visible at the four positions R6a, R6b, R7a, and R7b, where the conductances tend to their neighboring integer values at $j = 6, 7$ and 8 . Adapted from Chen S, Ribeiro-Palau R, Yang K, Watanabe K, Taniguchi T, Hone J, Goerbig MO, Dean CR (2019) Competing fractional quantum hall and electron solid phases in graphene. *Physical Review Letters* 122: 026802. <https://doi.org/10.1103/PhysRevLett.122.026802>.

integer value of j . The corresponding effect in graphene, which has been observed in 2019 (Chen et al., 2019), is shown in Fig. 6, where e.g., the $31/5$ state (at $1/5$ filling of the $n = 2$ LL) is flanked by two plateaus at $j = 6$. While the plateau on the left-hand side can be understood in terms of single-particle localization of the few electrons occupying the lowest spin-valley branch of the $n = 2$ LL, this is unlikely the case on the right-hand side (around $V_{tg} \simeq 7$ V). Theoretical calculations (Knoester et al., 2016; Chen et al., 2019) indicate that the FQHE $1/5$ Laughlin state competes with a Wigner crystal that is extremely close in energy at this filling factor. Precisely at $\nu = 31/5$, the FQHE state is lower in energy than the Wigner crystal, but once the filling factor is swept away from this precise value, the excited (gapped) quasiparticles or quasiholes raise the energy of the liquid states rapidly above that of the Wigner crystal, which becomes thus the ground state on both sides of the FQHE state and that gives rise to the insulating (IQHE) response there.

Conclusion

In conclusion, the observation of the FQHE and related correlated electronic phases in graphene corroborates the universality of the phenomenon: it is due to repulsive electronic interactions between electrons inside a single partially filled LL, in which the electrons' kinetic energy is frozen. In addition to this flat-band scenario, which one may encounter also in other situations in condensed-matter systems, the chirality of the quantum states, inherited from the classical cyclotron motion with a specific sense imposed by the orientation of the magnetic field, turns out to play an essential role in the formation of these exotic correlated states. The particularity of graphene is twofold: first, the states inherit the fourfold spin-valley degeneracy from the low-energy bands of graphene, and the associated $SU(4)$ symmetry is to great extent respected by the leading Coulomb repulsion; second, the specific spinorial form of the wave functions of graphene electrons yields slightly different wave-function overlaps as compared to the more conventional (GaAs) semiconductor heterostructures. Similarly, bilayer graphene is yet another version of a multi-component quantum-Hall system; in addition to the fourfold spin-valley degeneracy, the LLs $n = 0$ and $n = 1$ are situated at zero energy, and one is therefore confronted with an eightfold degeneracy here (Novoselov et al., 2006). However, since the wave functions are different in the two LLs $n = 0$ and $n = 1$, the Coulomb interaction is not symmetric in this index so that there is no $SU(8)$ symmetry as one might have expected at the beginning. Furthermore, the energy difference between the two layers and thus indirectly a *valley Zeeman effect* can be tuned by an electric field applied perpendicular to the 2D system such that there is an interesting controllable tunability in this system, as it has been proposed theoretically (Apalkov and Chakraborty, 2010) and measured experimentally (Maher et al., 2014). In this framework it is also interesting to notice that the situation between monolayer and bilayer graphene can to some extent be interpolated in layered systems where two graphene monolayers are separated by an insulating h-BN film of variable thickness. While for large thickness ($d \gg l_B$) the monolayers are essentially decoupled, and one would expect simply to

measure twice a monolayer quantum Hall effect, the interlayer coupling becomes stronger in the opposite limit ($d \ll l_B$) of thin h-BN layers. In the latter limit, novel interlayer-correlated FQHE states have indeed been observed experimentally (Liu et al., 2019).

We have mainly explored, in this short review, the consequences of the SU(4) symmetry, which does not only impact in an unexpected manner the FQHE states in the form of highly non-monotonic spin-valley polarizations when increasing the filling factor in the zero-energy $n = 0$ LL, but also the QHFM states that are formed at integer fillings beyond the particular graphene-IQHE sequence $\nu = \pm 2(2n + 1)$. The QHFM phases, which are also relevant for many FQHE states that come along with certain forms of spin-valley polarization, host not only novel magnon types that are absent in conventional quantum-Hall systems with only the spin as an internal degree of freedom, but also a rich zoo of exotic skyrmions. While the theoretical classification of the QHFM states, as well as the spin-valley magnons and the skyrmions, is now rather complete, as a function of the subleading SU(4)-symmetry-breaking terms, the experimental investigation of these states has just started. As for the skyrmions, a promising first step has been made by scanning-tunneling-spectroscopic measurements that are capable of monitoring the particular sublattice occupation for valley-skyrmions with a spatially varying valley polarization (Liu et al., 2022; Coissard et al., 2022). In the case of magnons, a very interesting way of probing these collective excitations is that via non-local transport measurements with a high voltage bias between the source and the drain. While this non-local transport is expected to happen only at the edges (at low bias), it has been shown that at higher bias, above the Zeeman energy scale, magnons can be excited at the edges that propagate through the sample bulk and relax at another local gate tuned at $\nu = \pm 2$ (Stepanov et al., 2018; Wei et al., 2018; Assouline et al., 2021; Pierce et al., 2022). This opens the perspective for a resistively-detected means of probing magnons in quantum-Hall systems, namely in graphene.

It is also interesting to mention that in line with the discovery of graphene as a particular 2D electronic system, other 2D crystals with unexpected electronic properties have been isolated. Most importantly, one should mention the family of 2D transition-metal dichalcogenides (e.g., MoS₂, MoSe₂, WS₂ or WSe₂). Similarly to graphene, the low-energy electronic properties of these materials may be described in terms of Dirac fermions, albeit massive Dirac fermions now. Moreover, these materials show a significant spin-orbit interaction, most prominently in the valence band so that the spin-valley components are frozen there. Namely, the $n = 0$ LL happens to occur in a single spin-valley component over a large magnetic-field and density range. In contrast to graphene, this allows for the study of the FQHE and other correlated phases in the ideal single-component limit for which the original theoretical trial wave functions (Laughlin, 1983; Jain, 1989; Moore and Read, 1991; Greiter et al., 1991) have been constructed. Recent compressibility measurements on high-quality WSe₂ samples have identified a large number of FQHE (Shi et al., 2020) and are a promising path to more detailed studies of the FQHE in these materials, corroborating both the universality of the phenomenon in 2D electronic systems in a strong magnetic field and the specificities of the different systems in terms of multi- vs. one-component manifestations of the effect.

Abstract

The fractional quantum Hall (FQH) effect at the filling factor $\nu = 5/2$ was discovered in GaAs heterostructures more than 35 years ago. Various topological orders have been proposed as possible candidates to describe this FQH state. Some of them possess non-Abelian anyon excitations, an entirely new type of quasiparticle with fascinating properties. If observed, non-Abelian anyons could offer fundamental building blocks of a topological quantum computer. Nevertheless, the nature of the FQH state at $\nu = 5/2$ is still under debate. In this chapter, we provide an overview of the theoretical background, numerical results, and experimental measurements pertaining to this special FQH state. Furthermore, we review some recent developments and their possible interpretations. Possible future directions toward resolving the nature of the $5/2$ state are also discussed.

Key points

- The $5/2$ fractional quantum Hall state was discovered more than 35 years ago but the nature of the physics underlying the state remains under intense debate.
- The exciting possibility of a paired $5/2$ state hosting exotic excitations with non-Abelian braid statistics led to considerable effort to prove their existence.
- Strong numerical and experimental evidence suggests that the $5/2$ state arises from pairing between composite fermions but the precise nature of the topological order defining the paired state remains unsettled.
- We review the culmination of experimental and theoretical studies on the $5/2$ state and discuss possible future directions for further inquiry.

Notations and acronyms

$\mathcal{C}$	Chern number
$E_{\text{Coul}} = e^2/\epsilon\ell_0$	Coulomb energy
$\hbar\omega_c = eB/mc$	Cyclotron energy
$J = \prod_{1 \leq i < j \leq N} (z_i - z_j)$	Jastrow factor
$\kappa = E_{\text{Coul}}/\hbar\omega_c$	Landau level mixing parameter
$\phi_0 = h/e$	Magnetic flux quantum
$\ell_0 = \sqrt{\hbar/eB}$	Magnetic length
$\mathcal{P}_{\text{SLL}}$	Projection operator to the second electronic Landau level
CFT	Conformal field theory
DMRG	Density matrix renormalization group
FQH	Fractional Quantum Hall
K_H	Thermal Hall conductance
LL	Landau level
N	Number of electrons
Q	Monopole strength in the spherical geometry
QPC	Quantum point contact
S	Topological shift
SET	Single electron transistor
w	Quantum well thickness
$z_k = x_k - iy_k$	Position of k -th electron in the xy -plane
$\nu = \rho\phi_0/B$	Landau level filling factor
ν	Electron filling factor

Introduction

The discovery of the FQH effect in two-dimensional semiconductor heterostructures started a new chapter in condensed matter physics [Tsui et al. \(1982\)](#). For a recent review on the basic concepts in FQH physics, see [Papić and Balram \(2022\)](#). In contrast to the conventional wisdom from Landau-Ginzburg theory, different quantum Hall states cannot be distinguished by spontaneously broken symmetries [Wen \(2004\)](#). Furthermore, early theoretical work suggested that the low-energy excitations in a FQH liquid are neither bosons nor fermions. Instead, they possess fractional charges [Laughlin \(1983a\)](#) and fractional braiding statistics [Arovas et al. \(1984\)](#), [Halperin \(1984\)](#) [see also the review article by [Feldman and Halperin, 2021](#)], which are known as anyons [Leinaas and Myrheim \(1977\)](#), [Wilczek \(1982\)](#). This special type of excitation turns out to be the basic ingredient in the formulation of topological order, which provides an effective description of different FQH states and distinguishes them by specifying the sets of possible anyons the FQH states can support [Wen \(2004\)](#). Note that the existence of fractional statistics has received strong support from very recent experiments [Bartolomei et al. \(2020\)](#), [Nakamura et al. \(2020\)](#), [Kundu et al. \(2022\)](#).

Many FQH states at different filling factors have been observed in various materials. Nearly all of them have odd denominators. For a summary of the observed FQH states, readers may refer to the lists in [Pan et al. \(2008\)](#) and [Hidalgo \(2022\)](#). Among them, the FQH state at filling factor $\nu = 5/2$ (dubbed as the 5/2 state below) in GaAs-GaAlAs quantum wells has attracted a tremendous amount of attention since its discovery [Willett et al. \(1987\)](#). This historical result is shown in [Fig. 1](#). The observation of the 5/2 state was surprising. It is a FQH state in the second LL (we define the lowest LL as the first LL). Also, it was the first FQH state with an even-denominator filling factor being observed in a single layer system.

The 5/2 state has been challenging to understand, as compared to other FQH states in the lowest LL which usually have odd-denominator filling factors. In particular, entirely new topological orders have been proposed as possible candidates to describe this special FQH state. Interestingly, some of them host non-Abelian anyons which may be useful in topological quantum computation [Das Sarma et al. \(2005\)](#), [Kitaev \(2003\)](#), [Nayak et al. \(2008\)](#).

Different types of experiments have been proposed and performed to probe the nature of the 5/2 state. Meanwhile, numerical simulation is another essential tool to study the problem. Evidence from both sources strongly suggests that the 5/2 state possesses non-Abelian topological order. Nevertheless, which one (or perhaps what combination of topological orders) is actually realized in real samples is still under considerable debate. A new twist on this 35-year old problem arose thanks to the exciting yet puzzling results from recent experiments [Banerjee et al. \(2018\)](#), [Dutta et al. \(2022a, 2022b\)](#) that we will discuss below. In order to resolve the apparent conflict between the recent experimental and existing numerical results, various scenarios have been proposed [Asasi and Mulligan \(2020\)](#), [Feldman \(2018\)](#), [Lian and Wang \(2018\)](#), [Ma and Feldman \(2019a\)](#), [Mross et al. \(2018\)](#), [Simon \(2018a\)](#), [Simon \(2018b\)](#), [Simon and Rosenow \(2020\)](#), [Wang et al. \(2018\)](#).

In this chapter, we provide an overview of the theoretical background, numerical studies, and experimental findings pertaining to the 5/2 state in GaAs heterostructures. Previous review articles on the same topic can be found in [Jiang and Wan \(2019\)](#), [Lin et al. \(2014\)](#), [Peterson \(2012\)](#), [Schreiber and Csáthy \(2020\)](#), [Willett \(2013\)](#). We will highlight recent developments in the past 5 years and outline possible future directions. Before diving into the details of the 5/2 state, it is worthwhile to mention that FQH states at

		Zibrov et al. (2017), Li et al. (2017)
		Huang et al. (2022)

Note that additional half-integer FQH states have been observed in higher Landau levels in monolayer graphene Kim et al. (2019), which are not listed here.

different halfinteger filling factors have been observed in GaAs heterostructures and other materials. They are summarized in Table 1. For a recent review on half-integer FQH states in graphene-based systems, see Apalkov and Charkaborty (2023). Note that an anomalous quantized plateau at $\nu = 3/2$ has been observed in monolayer GaAs systems with gate-defined confined regions Fu et al. (2019), Hayafuchi et al. (2022), Yan et al. (2022). However, this plateau is believed to emerge from a larger filling factor in the bulk. Thus, its nature might be very different from a genuine half-integer FQH state.

We note the present chapter is different from (most) other chapters, as it covers a topic that is currently being studied very actively, and this ongoing research will likely continue for quite some time. We thus do not have the final word, but instead try to provide some balanced guidance to people who are interested in this subject, in particular those who may want to contribute to it in the future. An unintended consequence of this is the chapter is considerably longer than (most) other chapters.

Theoretical background

When a two-dimensional electron gas is placed under a strong perpendicular magnetic field, the electron kinetic energy is quantized into LLs. Consequently, the kinetic energy of electron is quenched, and the energetics is dominated by the strong correlation between electrons Girvin and Yang (2019). A minimal Hamiltonian for the FQH regime is Laughlin (1983b):

$$H = \frac{e^2}{\epsilon \ell_0} \mathcal{P}_{\text{SLL}} \sum_{i < j} \frac{1}{|z_i - z_j|} \mathcal{P}_{\text{SLL}} \quad (1)$$

where $\mathcal{P}_{\text{SLL}}$ projects the repulsive Coulomb interaction between electrons into a single LL, $z_j = x_j - iy_j$ denotes the complex coordinates of electrons in the xy -plane (we assume the magnetic field points upward), e is the electron charge, and ϵ is the dielectric constant of the host semiconductor. Eq. (1) assumes an infinitely thin plane and an infinite LL splitting (no LL mixing). The former can be easily fixed by including a finite extent of the electron wave function along the perpendicular direction (often referred to as sub-band wave function) when calculating the effective 2D Coulomb potential, while the latter can be corrected by modifying the form of the interaction [Das Sarma and Pinczuk \(1996\)](#), [Jain \(2007\)](#). Furthermore, Eq. (1) assumes no electron spin. If we include the spin degree of freedom we must also include a Zeeman term in Eq. (1). For a detailed discussion on different energy scales in FQH states in GaAs heterostructures, and the corresponding justification for Eq. (1), interested readers may refer to [Papić and Balram \(2022\)](#).

Eq. (1) contains only a single interaction term. As a result, standard perturbation theory becomes inapplicable in studying FQH physics, which is solely determined by ν (once the interaction is fixed). The seminal work by Jain introduced the theory of composite fermions which is particularly intuitive in revealing how ν controls the physics [Jain \(1989a\)](#).

Theory of composite fermions

In a first approximation, a composite fermion is formed by attaching an even number $2p$ of magnetic flux quanta to an electron [Jain \(2007\)](#). Here, we only focus on the situation in which each composite fermion carries two magnetic flux quanta ($p = 1$). The number density of electrons in the two-dimensional electron gas satisfies $\rho = \nu B / \phi_0$, where $\phi_0 = h/e$ is the magnetic flux quantum. Due to flux attachment, the composite fermions experience a reduced effective magnetic field B_{eff} . This is illustrated in [Fig. 2](#). Under the mean field approximation,

$$B_{\text{eff}} = B - 2\rho\phi_0 = B(1 - 2\nu). \quad (2)$$

Since B_{eff} and B are different but the number density of electrons equals that of the composite fermions, the effective filling factor of composite fermions differ from the filling factor of electrons. Then by analogy to the integer quantum Hall effect, the integer quantum Hall state of composite fermions filling n_{CF} effective LLs (or the so-called Λ levels) corresponds to the FQH state of electrons at $\nu = n_{\text{CF}} / (2n_{\text{CF}} \pm 1)$. Here, the sign $\pm$ denotes the direction of the residual magnetic field experienced by the composite fermions. If it is parallel (anti-parallel) to the original field B , then the sign is $+$ ($-$).

At half filling of the lowest LL, $\nu = 1/2$, Eq. (2) predicts that the composite fermions experience a zero average magnetic field. This supports the absence of a FQH state at $\nu = 1/2$ in monolayer GaAs heterostructures. On the other hand, the ground state of electrons in a half-filled LL is a composite fermion Fermi liquid with a well-defined Fermi surface [Halperin et al. \(1993\)](#), [Kalmeyer and Zhang \(1992\)](#). Both the existence of composite fermions and the formation of a composite fermion Fermi surface at $\nu = 1/2$ have received strong experimental support [Goldman et al. \(1994\)](#), [Hossain et al. \(2020\)](#), [Kamburov et al. \(2014\)](#), [Kang et al. \(1993\)](#), [Smet et al. \(1996\)](#), [Willett et al. \(1993, 1999\)](#).

A possible starting point for studying FQH states at $\nu > 1$ is to simply focus on the partially filled LL(s). The above would then suggest that at $\nu = 5/2 = 2 + 1/2$ there would exist a gapless state and no FQH. But then how can we understand the presence of an energy gap to support the observed Hall plateau at $\nu = 5/2$? Previous approaches such as the hierarchical construction [Haldane \(1983\)](#), [Halperin \(1984\)](#) cannot directly explain gapped FQH states at even-denominator filling factors.

Wave function construction is central to the composite fermion ansatz and can be used to make progress. The microscopic flux attachment process defining the composite fermion wave function at total magnetic field B from an effective field at B_{eff} is given by [Jain \(1989a\)](#):

Fig. 2 Illustration of composite fermions (CFs). Left panel: Electrons in an external magnetic field B . Right panel: Composite fermions formed by attaching two magnetic flux quanta to each electron. The effective magnetic field experienced by the composite fermions is B_{eff} , which is different from B . The number of arrows indicates the number of magnetic flux quanta in the system.

$$\Psi^B = J^{2p} \psi^{B_{\text{eff}}} \quad (3)$$

where Ψ^B is an ansatz state of Eq. (1), J^{2p} is a Jastrow factor attaching an even number of vortices ($2p$) to each electron, and $\psi^{B_{\text{eff}}}$ is a fermionic wave function at an effective field B_{eff} that results from projection into a single LL Jain and Kamilla (1997). In the symmetric gauge we have, for N particles:

$$J = \prod_{i < j}^N (z_i - z_j) \quad (4)$$

where we see that J vanishes if two particles occupy the same location. J implements vortex attachment Read (1989, 1994, 1996) which can be approximated by flux attachment in effective theories. Here we have used the terms vortex and flux attachment interchangeably with the understanding that they are not exactly equivalent Murthy and Shankar (2003), Jain (2007).

Ψ^B describes a large class of possible ansatz ground states because we are free to choose $\psi^{B_{\text{eff}}}$. In the simplest setting we assume that $\psi^{B_{\text{eff}}}$ describes weakly interacting fermions. For example, Eq. (3) reduces to the Laughlin wave function at $\nu = 1/(2p + 1)$ Laughlin (1983a) if we set $\psi^{B_{\text{eff}}}$ to be an integer filled state of composite fermions at effective filling of $n_{\text{CF}} = 1$ Jain (1989a, 2007). We therefore see that the Laughlin states form a subset of states within the composite fermion wave function formalism.

A large class of states at half filling are also captured by Ψ^B . The composite fermion Fermi liquid Halperin et al. (1993) arises when we assume a filled Fermi sea at zero effective field ($n_{\text{CF}} \rightarrow \infty$) Rezayi and Read (1994) for $\psi^{B_{\text{eff}}}$. Here we have a gapless state that accurately captures the essential physics of the half-filled lowest LL Jain (2007). But in the following we discuss gapped examples of $\psi^{B_{\text{eff}}}$, relevant for even filling, specifically paired states, that yield energetically competitive ansatz wave functions for half filling of the second LL.

Paired quantum Hall states

The even denominator in the filling factor indicates that the $5/2$ state may originate from bosonic entities formed by electrons or composite fermions. Different from the original description with strongly correlated electrons, the effective interaction between composite fermions is much weaker. Similar to the case of $\nu = 1/2$, a composite fermion Fermi liquid is formed when the system has filling factor $5/2$. However, the effective interaction between composite fermions becomes weakly attractive at $\nu = 5/2$ and leads to a Cooper instability Scarola et al. (2000a). It is believed that the pairing between composite fermions gives rise to the gapped FQH state at $\nu = 5/2$ and other half-integer filling factors. This idea is illustrated in Fig. 3. This motivates ansatz states where $\psi^{B_{\text{eff}}}$ is an eigenstate of an effective pairing Hamiltonian Read and Green (2000).

The pairing Hamiltonian of Bardeen-Cooper-Schrieffer (BCS) takes the form:

$$H_{\text{BCS}} = \sum_k \left[\left(\frac{\hbar^2 k^2}{2m^*} - \mu \right) c_k^\dagger c_k + \frac{1}{2} \left(\Delta_k^* c_{-k} c_k + \Delta_k c_k^\dagger c_{-k}^\dagger \right) \right]. \quad (5)$$

Here, c_k and $c_k^\dagger$ are the second quantized operators for composite fermions, with the index k labeling the momentum. We assume the composite fermions are spin-polarized in this section and have thus suppressed the spin index. The symbols m^* and μ label the effective mass and chemical potential of composite fermions, respectively. Importantly, both m^* and μ are non-perturbative and due solely to the Coulomb interaction between electrons.

Knowing that composite fermions can form Cooper pairs does not completely determine the nature of the $5/2$ state. Different pairing channels with different gap functions Δ_k lead to different possible phases Read and Green (2000). Which one or what combination of these states are actually realized in a realistic experimental sample may depend sensitively on the microscopic details and experimental conditions. Notice that we use the terminologies, “states” and “topological orders” (sometimes abbreviated as orders) interchangeably in the following discussion.

Fig. 3 Pairing of composite fermions in the $\nu = 5/2$ and other half-integer FQH states. The red dots are electrons. Each of them is attached to two magnetic flux quanta marked by black arrows and form a composite fermion. These composite fermions form Cooper pairs (grouped by the red ovals in the figure), that gives rise to a gapped phase at half-integer filling factors.

Pfaffian (Moore-Read) state

The Pfaffian state (also known as the Moore-Read state) has the following wave function [Moore and Read \(1991\)](#):

$$\Psi_{\text{Pf}}(\{z_i\}) = J^2 \text{Pf} \left(\frac{1}{z_i - z_j} \right) \exp \left(- \sum_i \frac{|z_i|^2}{4\ell_0^2} \right). \quad (6)$$

The attachment of two flux quanta to each electron is implemented by the Jastrow factor, which also fixes the filling factor to be $\nu = 1/2$. The Gaussian factor is ubiquitous in every quantum Hall wave function, which originates from the eigenfunctions of LLs in the symmetric gauge [Prange and Girvin \(1987\)](#). This factor will be dropped in the following discussion. Finally, the Pfaffian factor is defined as

$$\text{Pf} \left(\frac{1}{z_i - z_j} \right) = \mathcal{A} \left(\frac{1}{z_1 - z_2} \frac{1}{z_3 - z_4} \dots \right), \quad (7)$$

where $\mathcal{A}$ denotes anti-symmetrization over the set of coordinates z_i . This “explains” the name of the Pfaffian state.

The Pfaffian wave function has several important features. The right hand side of Eq. (7) can be understood as a real-space BCS paired state at zero effective magnetic field [Read and Green \(2000\)](#), [Schrieffer \(1999\)](#). Ψ_{Pf} is therefore gapped flowing to the composite fermion BCS gap. Ψ_{Pf} is also an exact zero energy ground state of an idealized three-body Hamiltonian [Greiter et al. \(1992\)](#), which will be further discussed in Section “Overview of numerical results”.

Eq. (6) is an ansatz state for the incompressible (gapped) state of electrons half filling of the lowest LL. To describe the $5/2$ state, we assume the electrons completely fill the lowest two LLs (one with spin up and another with spin down polarizations), and the Pfaffian wave function describes the fully polarized electrons in the half filled second LL only [Greiter et al. \(1992\)](#), [Moore and Read \(1991\)](#), [Read and Green \(2000\)](#). Note that wave functions for FQH states in higher LLs can be generated systematically by acting LL raising operators on a wave function defined in the lowest LL [Girvin and Yang \(2019\)](#). For this reason we can always represent a wave function in any LL by its lowest LL counterpart, which is what we do throughout this chapter unless noted otherwise.

Conformal field theory description

Historically, the wave function in Eq. (6) was introduced in [Moore and Read \(1991\)](#) via conformal field theory (CFT). CFT has since become a powerful tool in studying quantum Hall physics [Hansson et al. \(2017\)](#). For details on CFT, readers may refer to the textbook [Francesco et al. \(1997\)](#). Here, we will only outline the basic ideas and state the necessary results directly.

For the Pfaffian state, the CFT description actually involves two different CFTs. The first part is a compactified holomorphic boson $\phi(z)$, which is responsible for the correct filling factor at $\nu = 1/2$ for the half-filled LL. The second part is the holomorphic Ising CFT which has three different primary fields as summarized in Table 2. In particular, there is a holomorphic Majorana fermion field $\psi(z)$ which has the scaling dimension $1/2$. The electron operator is defined as

$$\hat{\Psi}_e(z_j) = \psi(z_j) \exp [2i\phi(z_j)], \quad (8)$$

which has scaling dimension $3/2$ indicating that it indeed represents a fermion. The wave function in Eq. (6) can now be interpreted as the correlation function between electron operators:

$$\Psi_{\text{Pf}}(\{z_j\}) = \prod_{j=1}^N \langle \hat{\Psi}_e(z_j) \hat{O}_{bg}(z_j) \rangle. \quad (9)$$

In the above equation, the background charge operator $\hat{O}_{bg}(z_j)$ ensures that the correlation function does not vanish. It is also responsible for reproducing the correct Gaussian factor in the wave function.

Table 2 Primary fields in the holomorphic Ising CFT (top table) and their fusion rules (bottom table).

Primary field		Scaling dimension	
I		0	
ψ		1/2	
σ		1/16	
$\times$	I	ψ	σ
I	I	ψ	σ
ψ	ψ	I	σ
σ	σ	σ	$\psi + I$

After defining the suitable electron operator in the CFT approach, all possible quasiparticles in the quantum Hall state can be deduced systematically. For example, consider the quasiparticle described by the CFT operator

$$\hat{\Psi}_{\text{qp}}(z) = \sigma(z)e^{i\alpha\phi(z)}, \quad (10)$$

where α is a constant that needs to be determined. The operator product expansion between the quasi-particle and the electron operators must be single-valued (or without any branch cut). This condition leads to $\alpha = n' + 1/2$, with n' being an arbitrary integer. In particular, $n' = 0, -1$ corresponds to quasiparticles with charges $\pm e/4$. The corresponding CFT operator has scaling dimension $1/8$, which is the most relevant operator among all possible operators for quasiparticles in the Pfaffian state. Interestingly, the fusion rule $\sigma \times \sigma = \psi + I$ indicates that these quasiparticles are non-Abelian anyons. This exciting feature has motivated many of the ongoing studies of $5/2$ state, in the hope of finding its potential applications in topological quantum computation Kitaev (2003), Nayak et al. (2008).

Edge theory

FQH states that are gapped in the bulk must nonetheless become gapless at the edges Halperin (1982). Effective low-energy theories have been used to model gapless edge states Wen (2004). Also, the bulk-edge correspondence suggests that different bulk topological orders usually have correspondingly different edge structures Cano et al. (2014), Dubail and Read (2011), Qi et al. (2012), Swingle and Senthil (2012), Yan et al. (2019). The knowledge of edge physics can provide invaluable insight into the nature of the underlying quantum Hall states. Hence, various types of experiments have been proposed and performed to probe the edge structure of different quantum Hall states. For a review of these edge probes, see Heiblum and Feldman (2020).

For the Pfaffian state, its edge structure can be deduced from the aforementioned CFT approach. Similar to the Laughlin state, the Pfaffian edge possesses a chiral Bose mode ϕ_c . The subscript c indicates that it is a charge mode. Its chirality, which corresponds to the downstream direction of propagation, is fixed by the direction of the external magnetic field. In addition, the Pfaffian edge has a chiral Majorana fermion mode ψ that is copropagating with the Bose mode Milovanović and Read (1996), Wan et al. (2006), Wen (1993). As a result, the Pfaffian edge is described by the Lagrangian density,

$$\mathcal{L}_{\text{Pf}} = -\frac{2}{4\pi} \partial_x \phi_c (\partial_t + v_c \partial_x) \phi_c + i\psi (\partial_t + v_n \partial_x) \psi. \quad (11)$$

The symbols v_c and v_n denote the speeds of the charge Bose mode and neutral Majorana fermion mode, respectively. Notice that a chiral Bose field and a chiral Majorana fermion field are present in both the bulk and the edge of the Pfaffian state. This feature is a manifestation of the bulk edge correspondence. In numerical simulations, v_c and v_n were found to satisfy $v_c \gg v_n$ due to Coulomb interaction Wan et al. (2008)—see Section “Overview of numerical results”. The charge density of the edge is completely governed by the Bose mode, given by $\rho(x) = -e\partial_x \phi_c / 2\pi$. Its corresponding edge channel contributes to an electrical Hall conductance $\sigma_{xy} = e^2/2h$. At $\nu = 5/2$, there are actually two more edge channels originating from the two completely filled LLs. Both of them are described by chiral Bose modes different from ϕ_c . Each of these integer channels contributes $\sigma_{xy} = e^2/h$, so the electrical Hall conductance $5e^2/2h$ at $\nu = 5/2$ follows. Unless otherwise specified, we will ignore the two integer channels in this section. The edge structure for the Pfaffian state is shown in Fig. 4.

Weak pairing of composite fermions

As previously mentioned, the FQH state at $\nu = 5/2$ is believed to originate from the pairing between composite fermions. The Pfaffian state in particular postulates a weak pairing phase [i.e., $\mu > 0$ in Eq. (5)] of composite fermions in the p -wave angular momentum channel Read and Green (2000). The corresponding gap function in Eq. (5) takes the form $\Delta_k = \Delta_0(k_x + ik_y)$. From this perspective, the Pfaffian factor in the wave function can be interpreted as the BCS wave function in position space representation. Furthermore, the Chern number of this weak pairing phase was evaluated to be $\mathcal{C} = 1$; an explicit calculation can be found in the Appendix A of Ma (2019). This indicates that the Pfaffian state is topologically nontrivial. It is reflected by the existence of a chiral Majorana fermion mode on the edge, which is also consistent with the breaking of time reversal symmetry in the p -wave BCS pairing channel.

Fig. 4 Edge structures of the Pfaffian, anti-Pfaffian (abbreviated as APf in the figure), and PH-Pfaffian states. Here, solid lines and dashed lines denote Bose modes and Majorana fermion modes, respectively. The chirality of the overall charge mode ϕ_c is defined as the downstream direction (pointing to the right). In the anti-Pfaffian state, the description of its edge structure depends on disorder. In the case of clean edge, there are two Bose charge modes ϕ_1 (integer mode) and $\phi_{1/2}$ (fractional mode). These two modes can be coupled by disorder. For sufficiently strong disorder, the edge is driven to the disorder-dominated fixed point and being described by an overall charge mode and three upstream Majorana fermion modes. Note that we have neglected the two additional integer Bose modes due to the two lower LLs which are present in the actual edge of the $5/2$ state.

Anti-Pfaffian state

When the effect of LL mixing is negligible, the particle-hole transformation is an exact symmetry in a half-filled LL. Thus, the particle-hole conjugate of the Pfaffian state provides another viable candidate to describe the 5/2 state. This motivated the introduction of the anti-Pfaffian state in [Levin et al. \(2007\)](#) and [Lee et al. \(2007\)](#). In principle, the wave function of the anti-Pfaffian state can be obtained systematically from particle-hole conjugating the Pfaffian wave function in Eq. (6) [Lee et al. \(2007\)](#). In fact, as discussed in Section “Overview of numerical results”, since most numerical studies consider the limit where particle-hole symmetry is exact, both the Pfaffian and anti-Pfaffian states are trivially related—they are particle-hole conjugate states to one another. Nevertheless, more recent numerical work has undertaken studies of the anti-Pfaffian state under various conditions.

Using the parton theory introduced in [Jain \(1989b\)](#), the $\bar{2}\bar{2}111$ parton state was proposed to describe the 5/2 state ([Balram et al., 2018a](#)). It was discovered that the $\bar{2}\bar{2}111$ parton state describes the same phase, and has a high numerical overlap with the wave function of the anti-Pfaffian state [Balram et al. \(2018a\)](#). Meanwhile, the parton state is much easier to use in numerics.

The anti-Pfaffian state has a more complicated edge structure than the Pfaffian. First, there is an integer Bose mode circulating on the edge in the downstream direction. Due to the particle-hole transformation, the chiralities of the Bose mode and the Majorana fermion mode on the original Pfaffian edge are reversed. As a result, there are three different edge modes in the anti-Pfaffian state as illustrated in [Fig. 4](#). In a real experimental sample, disorder exists and couples the edge modes. When this coupling is sufficiently strong, the anti-Pfaffian edge is driven to the disorder-dominated phase, which consists of a single downstream charge Bose mode and three upstream neutral Majorana fermion modes [Lee et al. \(2007\)](#), [Levin et al. \(2007\)](#). Furthermore, these Majorana fermion modes exhibit an emergent SO(3) symmetry and have the same velocity $\bar{v}_n$. As a result, the edge can be described by

$$\mathcal{L}_{\text{Apf}} = -\frac{2}{4\pi} \partial_x \phi_c (\partial_t + v_c \partial_x) \phi_c + i \sum_{j=1}^3 \psi_j (\partial_t - \bar{v}_n \partial_x) \psi_j. \quad (12)$$

The anti-Pfaffian state also hosts non-Abelian anyons with charges $\pm e/4$. Since the edge is not maximally chiral, the scaling dimensions of CFT operators for quasiparticles are non-universal. The $e/4$ anyon has a minimum scaling dimension of 1/4, which is achieved in the aforementioned disorder-dominated phase. The scaling dimension is larger than the value of 1/8 in the Pfaffian state. This difference turns out to be important when one considers tunneling experiments discussed in Section “Early experiments and evidence for/against non-Abelian states”.

In the weak pairing picture, the anti-Pfaffian state is interpreted as the superconducting phase arising from f -wave pairing between composite fermions. The gap function in Eq. (5) takes the form $\Delta_k = \Delta_0(k_x - ik_y)^3$. Note that the corresponding Bogoliubov-de Gennes (BdG) Hamiltonian has Chern number $\mathcal{C} = -3$. This explains the difference between the numbers of chiral Majorana fermion edge modes in Pfaffian and anti-Pfaffian states.

PH-Pfaffian state

Recently, the particle-hole Pfaffian (PH-Pfaffian) state has attracted a considerable amount of attention as a candidate 5/2 state in GaAs heterostructures. It was originally introduced in the theory of Dirac composite fermions, which is a theory that preserves particle-hole symmetry explicitly in the half-filled LL [Son \(2015, 2016\)](#). In particular, the PH-Pfaffian state can be viewed as arising from s -wave pairing between Dirac composite fermions. This translates into a p -wave pairing (with the opposite chirality as the Pfaffian) between ordinary composite fermions, in which the corresponding BdG Hamiltonian has Chern number $\mathcal{C} = -1$. Different from the Pfaffian and anti-Pfaffian states, the PH-Pfaffian state is particle-hole symmetric. It is worth noting that a similar state known as the time-reversal symmetry preserving Pfaffian ($\mathcal{T}$ -Pfaffian) was introduced to describe the $\mathcal{T}$ -invariant surface state of topological insulators [Bonderson et al. \(2013\)](#), [Fidkowski et al. \(2013\)](#). Nevertheless, the realization of PH-Pfaffian order does not require the system itself to preserve particle-hole symmetry [Zucker and Feldman \(2016\)](#)—after all, LL mixing and other effects present in real experimental systems explicitly break particle-hole symmetry.

The edge structure of the PH-Pfaffian state can be deduced from its particle hole symmetry. After a particle hole transformation, the resulting edge theory has central charge $1-c$, with c being the central charge of the original edge theory. In order for the edge to be particle-hole symmetric, c needs to be 1/2. Furthermore, there must be a downstream Bose mode ϕ_c , such that its corresponding edge channel leads to the correct electrical Hall conductance of $\sigma_{xy} = e^2/2h$. Therefore, the remaining edge mode must be an upstream Majorana fermion mode ψ . Hence, the PH-Pfaffian edge is described by the Lagrangian density,

$$\mathcal{L}_{\text{PH-Pf}} = -\frac{2}{4\pi} \partial_x \phi_c (\partial_t + v_c \partial_x) \phi_c + i \psi (\partial_t - v_n \partial_x) \psi. \quad (13)$$

The edge structure is shown in [Fig. 4](#).

After deducing the edge structure, it is straightforward to formulate the CFT description of the bulk. The electron operator with the appropriate chirality and scaling dimension is $\hat{\Psi}_e(z) = \psi(\bar{z}) \exp[2i\phi(z)]$. Here, $\bar{z}$ denotes the complex conjugation of z . Physically, the anti-holomorphicity of ψ originates from its upstream chirality at the edge. By evaluating the correlation function

between electron operators, a possible wave function for the PH-Pfaffian state was written down explicitly in Zucker and Feldman (2016):

$$\Psi_{\text{PH-Pf}}(\{z_i\}) = J^2 \text{Pf} \left(\frac{1}{\bar{z}_i - \bar{z}_j} \right). \quad (14)$$

To be studied in numerics, one needs to project the wave function into a single LL, which turns out to be subtle. An alternative wave function can be obtained based on the argument of negative flux attachment Jolicœur (2007). However, there is limited numerical support for either wave function to describe a gapped phase after the lowest LL projection. This issue will be discussed more in Section “Overview of numerical results”.

Unified description: Kitaev’s 16-fold way

Based on different approaches such as trial wave functions, CFT, parton theory, and particle-hole conjugation, other possible candidates for describing FQH states at half-integer filling factors were introduced. They are listed in Table 3. Some of them may be irrelevant to the 5/2 state in monolayer GaAs quantum wells, but they may describe different half-integer states in other materials listed in Table 1. For example, the spin-unpolarized version of Halperin-331 state is believed to describe the FQH state at $\nu = 1/2$ in bilayer systems and wide quantum wells. It has been studied widely numerically He et al. (1993), Peterson and Das Sarma (2010), Peterson et al. (2010), Scarola et al. (2010), Scarola and Jain (2001), Yoshioka et al. (1989). Also, the 221 parton state may describe

Table 3 Possible topological orders in the 16-fold way for the spin-polarized 5/2 state, and their predicted experimental signatures and topological shifts.

$\mathcal{C}$	Name	References	$g_e/4$	κ_H	Even-odd effect?	Shift
0	K = 8	(i, ii)	1/8	3	No	3

Here, the possibilities of edge reconstruction and Majorana gapping are ignored. The first column shows the Chern numbers of the topological orders. Topological orders with odd (even) are non-Abelian (Abelian). On the edges of these topological orders, there are chiral Majorana fermion modes. The orders with have upstream neutral modes. Since a pair of Majorana fermion modes can be combined into a neutral Bose mode, there is no unpaired Majorana fermion mode at even. In the second and third columns, we provide the usual names of the topological orders in the existing literature if any (see the end of this caption for the key of the references). The smallest possible charge anyon has the charge $e/4$. When the edge is in the disorder-dominated phase, the fourth column gives the tunneling exponents for the $e/4$ anyons. These values are boldfaced when the $e/4$ anyon is the most relevant quasiparticle. The fifth column lists the thermal Hall conductance in units of $\kappa_0 = \pi^2 k_B^2 / 73h$. They are half-integers (integers) for non-Abelian orders (Abelian orders). All non-Abelian orders should demonstrate the even-odd effect in a Fabry-Pérot interferometer. Abelian orders (except the K = 8 state) may also show the same effect if they possess flavor symmetry. These are listed in the sixth column. The last column shows the topological shifts for different topological orders, which are important for numerical studies performed on the spherical geometry. Note that the shifts for Abelian orders here are for the spin-polarized states. For the spin-unpolarized Halperin-331 state, the shift is 3 but not 5 Wen (1993). For Abelian orders with the shifts are unpublished. A brief overview of different experimental techniques are given in Section “Early experiments and evidence for/against non-Abelian states”, “Transport and optics: Bulk energy gap”, “Density dependence”, “Disorder, mobility, and sample design”, “In-plane magnetic field and sample tilt impacts the bulk gap”, “Optical probes of the bulk gap”, “Surface acoustic waves, geometric resonance transport, light scattering, and Knight shift: Spin polarization”, “Surface acoustic waves and geometric resonance”, “Transport”, “Light scattering”, “Knight shift”, “Tunneling with QPCs and SETs: Quasiparticle charge and edge exponents”, “QPC tunneling”, “SETs”, “Edge exponents from tunneling conductance”, “Noise in QPCs: Upstream neutral mode”, “Interferometry: Quasiparticle charge and braiding”, “Interferometry and charge”, “Interferometry and braiding”, “Summary of early experimental findings”, “Recent surprises and puzzles”, “Experimental results”, “Possible interpretations”, “Bulk edge correspondence: PH-Pfaffian”, “Disorder induced Pf-APf domain walls”, “Partial equilibration on anti-Pfaffian edges”, “Recent and ongoing developments”, “Temperature dependence of ℓ_{eq} ”, “Interface experiments”, “Summary of recent developments”, “Future directions”. For a detailed discussion, see Ma and Feldman (2019b). The labels for the references in which the topological orders were introduced are (i) Halperin (1983); (ii) Wen and Zee (1992a); (iii) Moore and Read (1991); (iv) Greiter et al. (1991); (v) Son (2015); (vi) Zucker and Feldman (2016); (vii) Yang and Feldman (2014); (viii) Yang (2015); (ix) Jain (1989b); (x) Jain (1990); (xi) Levin et al. (2007); (xii) Lee et al. (2007); (xiii) Balram et al. (2018a); (xiv) Yang and Feldman (2013).

half-integer states in graphene systems Kim et al. (2019), Wu et al. (2017). Given that these topological orders were introduced via different approaches, it is desirable to have a unified and systematic description.

The possible types of topological orders or phases in the paired quantum Hall state depend on the spin polarization of electrons and the associated composite fermions. Experimental results suggest that the 5/2 state observed in GaAs samples at the electron density $\rho \sim (2-3) \times 10^{11} \text{ cm}^{-2}$ are spin polarized (see Section “Early experiments and evidence for/against non-Abelian states”). This conclusion is also supported from numerical work (see Section “Overview of numerical results”). Furthermore, a recent geometric resonance measurement performed very close to $\nu = 5/2$ has provided strong evidence of a fully spin-polarized Fermi sea for composite fermions Hossain et al. (2018).

There are an infinite number of possible channels for pairing composite fermions which would, at first, appear to give an infinitely long list of possible topological orders for describing the 5/2 state. But the classification of possible theories is constrained. The classification of topological orders is based on the types of anyons they possess Wen (2004). When two topological orders have the same set of anyons (i.e., all fractional charges, braiding statistics, and fusion rules are the same), then they are equivalent. Following the above definition, there are only 16 possible topological orders from pairing spin-polarized composite fermions. This property is known as Kitaev’s 16-fold way Kitaev (2006). Therefore, most of the existing candidates for describing the spin-polarized 5/2 state are particular members in the 16-fold way Ma and Feldman (2019b). The original work by Kitaev considered topological orders with neutral excitations only, however, charge excitations exist in the 5/2 state. It was shown that all of these topological orders can host charge $\pm e/4$ anyons. The Chern number $\mathcal{C}$ of the topological order carries important information, which will be discussed below. Based on the 16-fold way description, various experimental signatures for different topological orders were predicted and summarized in Table 3.

Properties of anyons

$\mathcal{C}$ can be identified as the Chern index in the original Kitaev’s 16-fold way, such that the properties of anyons in each topological order can be inferred. The eight orders with even $\mathcal{C}$ are Abelian, whereas the eight with odd $\mathcal{C}$ are non-Abelian. In the latter case, quasiparticles with charges $(2m+1)e/4$ (where $m \in \mathbb{Z}$) are non-Abelian anyons. For the former case, there are two different types (or flavors) of Abelian anyons for quasiparticles with charges $(2m+1)e/4$. The scaling dimensions of the electron operator, and the operators for quasiparticles with charges $\pm e/4$ and $\pm e/2$ are Ma and Feldman (2019b)

$$\Delta_e = \frac{3}{2}, \quad \Delta_{e/2} = \frac{1}{4}, \quad \text{and} \quad \Delta_{e/4} = \frac{|\mathcal{C}|+1}{16}. \quad (15)$$

These results are useful in analyzing quasiparticle tunneling conductance experiments. In particular, the low-temperature electrical conductance, in the idealized case, obeys $\sigma \sim T^{2g-2}$, where $g = 2\Delta$ is the tunneling exponent Wen (2004) and T is temperature. The value of g depends on the type of quasiparticles participating in the tunneling process, which can have different scaling dimension Δ for different candidate states for the 5/2 FQH state.

Edge theory

The Chern number $\mathcal{C}$ also specifies the number and chirality of the Majorana fermion modes on the edge of the topologically ordered phase. Suppose the edge is equilibrated by disorder, then its appropriate description consists of an overall charge mode ϕ_c and a collection of Majorana fermion modes ψ_j . Since a pair of counter propagating Majorana fermion modes can be gapped out or become localized due to electron tunneling on the edge, we can assume all ψ_j have the same chirality. In addition, these ψ_j exhibit an emergent $\text{SO}(|\mathcal{C}|)$ symmetry in the low temperature limit (i.e., the symmetry breaking terms are irrelevant in the renormalization group sense) and have the same velocity $\bar{v}_n$. For more details, see Yang and Feldman (2013, 2014). From the above discussion, the edge of a topologically ordered phase with Chern number $\mathcal{C}$ is described by Feldman and Halperin (2021), Ma and Feldman (2019b):

$$\mathcal{L} = -\frac{2}{4\pi} \partial_x \phi_c (\partial_x + v_c \partial_x) \phi_c + i \sum_{j=1}^{|\mathcal{C}|} \psi_j [\partial_t + \text{sgn}(\mathcal{C}) \bar{v}_n \partial_x] \psi_j. \quad (16)$$

Since a pair of ψ_j can be combined into a complex fermion mode and becomes a Bose mode upon bosonization, there are $|\mathcal{C}|/2$ neutral chiral Bose modes when $\mathcal{C}$ is even. Hence, Abelian orders such as the unpolarized Halperin-331 state do not have unpaired Majorana fermion modes on the edge. The existence or absence of unpaired Majorana fermion modes can be probed in the thermal Hall conductance experiments. The edge structures are different for topological orders with $\mathcal{C}$ and $\mathcal{C} + 16m$ (where $m \in \mathbb{Z}$), but the 16-fold way implies that they have the same set of anyons. Hence, they are equivalent.

Edge reconstruction and Majorana fermion gapping lead to additional candidates for describing the 5/2 edge state. These include the Majorana-gapped edge-reconstructed Pfaffian state and the Majorana gapped anti-Pfaffian state Overbosch and Wen (2008). However, their realization in real GaAs samples is not supported by tunneling conductance experiments or upstream noise measurements (see Section “Early experiments and evidence for/against non-Abelian states”).

Bulk collective excitations

Incompressible FQH states must be gapped at all wavevectors. It turns out that lowest LL FQH states at filling $n_{\text{CF}}/(2p_{\text{CF}} \pm 1)$ possesses a low-lying intra-LL branch of collective modes that were first identified numerically at $1/3$ filling [Haldane and Rezayi \(1985\)](#). These modes are accurately captured by the composite fermion wave functions.

Quasiparticle-quasihole pairs inserted into $\psi^{B_{\text{eff}}}$ define composite fermion magnetoexcitons. Composite fermion magnetoexcitons have a quasiparticle-quasihole spacing proportional to their wavevector. The ensuing collective mode dispersion reveals neutral roton modes at intermediate wavevectors and a well separated quasiparticle-quasihole pair at large wavevectors (Alternatively, they can be viewed as a density wave created on top of the otherwise uniform ground state.).

Composite fermion magnetoexciton wave functions have been systematically compared against unbiased numerical results and have been found to be essentially exact in the lowest LL [Jain \(2007\)](#). The gaps predicted from wave function energetics compare well with experiment as well [Hirjibehedin et al. \(2005\)](#), [Kang et al. \(2001\)](#), [Kukushkin et al. \(2009\)](#), [Scarola et al. \(2000b\)](#). These collective modes have also been incorporated as central features of composite fermion effective field theories of lowest LL FQH states [Lopez and Fradkin \(1993\)](#), [Murthy and Shankar \(2003\)](#). Unfortunately, accurate and well tested wave functions of the quasiparticle-quasihole excitations at $5/2$ are still lacking.

A very useful approximation to FQH collective mode theory was originally formulated by Girvin, MacDonald and Platzman (GMP) [Girvin et al. \(1985\)](#). It only requires a ground state ansatz and captures the fact that these collective modes are akin to density waves. The GMP excitation is gapped and neutral as well. In the long-wavelength limit, the GMP mode behaves as a spin-2 mode analogous to a graviton [Golkar et al. \(2016a\)](#), [Yang \(2016\)](#), [Yang et al. \(2012\)](#). This graviton mode is chiral with its chirality (or polarization) depending on the FQH state [Liou et al. \(2019\)](#).

The GMP approximation was used to study the low lying excitations of the $5/2$ state [Park and Jain \(2000\)](#), [Wright and Rosenow \(2012\)](#). Moreover, the GMP modes in Pfaffian, anti-Pfaffian, and PH-Pfaffian states have different polarizations [Haldane et al. \(2021\)](#), [Nguyen and Son \(2021\)](#). As reviewed in Section “Future directions”, this feature is useful in probing the nature of the $5/2$ state. An additional type of collective excitation from Cooper-pair breaking was predicted for the Pfaffian state [Greiter et al. \(1991\)](#), which is dubbed as the neutral fermion mode [Bonderson et al. \(2011\)](#), [Möller et al. \(2011\)](#). It is gravitino-like and has spin $3/2$ in the long-wavelength limit [Yang et al. \(2012\)](#). In the Pfaffian state, the GMP and neutral fermion modes can be viewed as superpartners [Gromov et al. \(2020\)](#). It is expected that neutral fermion modes also exist in other non-Abelian candidates in the 16-fold way. However, no related study has been reported.

Overview of numerical results

Numerical support for the Laughlin state and composite fermion theory of the FQH effect in the lowest LL was definitive and set an extremely high standard. For example, finite size effects are reduced due to the large energy gaps and fast spatial decay of correlations. Wave function overlaps between exact Coulomb ground states and the composite fermion states (including the Laughlin state) approach unity [Jain \(2007\)](#), [Prange and Girvin \(1987\)](#). Numerical support for the Pfaffian description of the FQH effect at $5/2$, while impressive as reviewed in this section, is less conclusive.

Early numerical support for the Pfaffian description of the $5/2$ state was provided in the seminal work by [Morf \(1998\)](#). Over the years, numerical work has continued to play an important role. Here we briefly discuss some technical details regarding the numerical approaches used in studies of the FQH effect before discussing important landmarks and results.

Numerical methods and geometries

The non-interacting basis states for the Hamiltonian consisting of only the electron-electron interaction, Eq. (1), are massively degenerate and there is no small parameter or normal state around which a perturbation theory can be formulated. An extremely useful parameterization, due to [Haldane \(1983\)](#) and discussed in more detail in [Prange and Girvin \(1987\)](#), reformulated the Hamiltonian into so-called Haldane pseudopotentials. Eq. (1) can be rewritten as

$$H = \sum_m V_{m,\text{two-body}}^{(n)} \sum_{i<j} \hat{P}_{ij}(m), \quad (17)$$

where $\hat{P}_{ij}(m)$ is a projection operator onto two particle states with relative angular momentum m and $V_{m,\text{two-body}}^{(n)}$ are the Haldane pseudopotentials in units of $e^2/\epsilon\ell_0$. $V_{m,\text{two-body}}^{(n)}$ is the interaction energy between two electrons with relative angular momentum m projected into the n -th electronic LL (the $n = 1$ corresponds to the second LL, sometimes called the first excited LL).

To study the FQH effect at $\nu = 5/2$, the simplest model Hamiltonian is Eq. (17) with the $V_m^{(1)}$ corresponding to the Haldane pseudopotentials for the Coulomb interaction between electrons confined to the second LL. The pure Coulomb interaction is an idealized situation because the magnetic field strength is taken to infinity (or equivalently the electron mass going to zero), i.e., the case of infinite spacing between LLs or zero LL mixing.

It turns out that LL mixing [Bishara and Nayak \(2009\)](#), [Peterson and Nayak \(2013\)](#), [Simon and Rezayi \(2013\)](#), [Sodemann and MacDonald \(2013\)](#) and the finite thickness [Peterson et al. \(2008a, 2008b\)](#) of the quasi-two-dimensional electron system are important effects for second LL physics which must be taken into account. Finite thickness is typically parameterized by the width of

the quantum well $w/\ell_0 \sim 2 - 3$ for GaAs samples [see Ando et al., 1982; Stern and Das Sarma, 1984; Zhang and Das Sarma, 1986] and LL mixing is parameterized by the ratio κ of the Coulomb interaction energy E_{Coul} to the cyclotron energy $\hbar\omega_c = eB/mc$ and depends inversely on the square root of the magnetic field strength:

$$\kappa = \frac{E_{\text{Coul}}}{\hbar\omega_c} \approx \frac{2.5}{\sqrt{B}}. \quad (18)$$

The second approximation is specific to GaAs heterostructures. Thus, when $\kappa \ll 1$, LL mixing can be ignored and the “pure” Coulomb Hamiltonian projected into the second LL is a good model. However, as discussed in Section “Early experiments and evidence for/against non-Abelian states” the FQH effect at $5/2$ has been observed over a wide range of magnetic field strengths: $1 \text{ T} \lesssim B \lesssim 30 \text{ T}$, corresponding to $2.5 \gtrsim \kappa \gtrsim 0.5$, hence, κ is never vanishingly small and is often sizable.

Besides the realistic (or idealized) Hamiltonian relevant for experimental systems mentioned above, there is a model Hamiltonian due to Greiter et al. (1992), which produces the Pfaffian as an exact zero-energy ground state. This (artificial) three-body Hamiltonian is written as

$$H_3 = \sum_{i < j < k} S_{ijk} \left\{ \nabla_i^2 [\delta(z_i - z_j) \nabla_k^4 \delta(z_i - z_k)] \right\} \quad (19)$$

where S_{ijk} symmetrizes over all permutations of ijk . The form of H_3 is due to the fact that the Pfaffian vanishes whenever three electrons coincide Greiter et al. (1991), see Eqs. (6) and (7). Note that H_3 breaks particle-hole symmetry explicitly as does the Pfaffian wave function. The particle-hole conjugate of H_3 , called $\bar{H}_3$, produces the anti-Pfaffian as an exact ground state Lee et al. (2007), Levin et al. (2007).

Three geometries are commonly utilized in numerical studies and pertinent details are discussed by Jain (2007). The experimental system is quasi-two-dimensional with edges created with confining potentials. For numerical convenience and simplicity this system is mapped to a quasi-two-dimensional one with periodic boundary conditions (the torus geometry), a rotationally symmetric system (the disk geometry), and a compact geometry where the electrons on the two-dimensional plane are mapped to the surface of a sphere with the perpendicular magnetic field produced by a magnetic monopole placed at the center (the spherical geometry). There is also the cylinder geometry (a torus with a cut) used primarily in DMRG calculations. Each geometry has pros and cons.

The torus geometry is perhaps the most straightforward Chakraborty and Pietiläinen (1995), Haldane (1985), Yoshioka (2002). The system is a parallelogram with periodic boundary conditions. The LL degeneracy per unit area is B/ϕ_0 and the filling factor is precisely defined as $\nu = \rho/(B/\phi_0)$. The energy eigenvalues are labeled by pseudo-momenta (k_x, k_y) . This geometry has genus one (it has a single hole) and allows a topological ground state degeneracy greater than one that can be leveraged to identify the topological order of an exact ground state.

In the spherical geometry Wu and Yang (1976, 1977) the electrons are placed on the surface of a sphere of constant radius $R = \sqrt{Q}\ell_0$ where Q is the strength of the Dirac magnetic monopole at the center of the sphere. The total magnetic flux through the surface of the sphere is $2Q\phi_0$ and $2Q$ is an integer due to Dirac’s quantization condition. The relationship between the number of electrons and the magnetic flux is given by

$$2Q = \nu^{-1}N - S \quad (20)$$

where S is an order-one number called the topological shift Wen and Niu (1990), Wen and Zee (1992b).

Different shifts S correspond to states with different topological orders. For example, the Pfaffian has $S = 3$ while the anti-Pfaffian has $S = -1$, see Table 3. The filling factor in this geometry is then defined as $\nu = \lim_{Q \rightarrow \infty} N/2|Q|$ and energy eigenstates are given as functions of total angular momentum L . This geometry has no edges and a finite degeneracy of $2(Q + n) + 1$ for the n -th LL. This makes the sphere especially convenient to study bulk physics, ground states and low-energy excitation spectra, and ansatz wave functions.

In the disk geometry, the single-particle states are especially simple Jain (2007). In fact, the disk geometry is utilized often when representing ansatz wave functions in real space and when calculating Haldane pseudopotentials of various interaction potentials. The disk geometry requires a confining potential to keep the electrons from repelling one another off to infinity. Since the disk geometry necessarily has an edge it can be used to study edge physics.

While all the numerical work has finite size effects due to the modest number of electrons that can be studied, i.e., up to about $N = 18$ for realistic Hamiltonians discussed in detail in Section “Competing phases and Landau level mixing” which has a total $L_z = 0$ subspace dimension of over 29 million states, the energy gap necessary for a FQH state to exist reduces the finite size effects substantially. See the Supplemental Materials of Balram and Wójs (2020) for the largest systems exactly diagonalized to date. We note that Monte Carlo simulations, which can treat on the order of hundreds of electrons, mostly involve the analysis of ansatz wave functions and not exact eigenstates.

Spin polarization

The FQH effect at $5/2$ remained puzzling for a dozen years after its experimental discovery by Willett et al. (1987). Initial “tilt-field” experiments showed a disappearing FQH plateau upon tilting the sample with respect to the magnetic field direction while keeping

the filling factor fixed. It was initially thought that the ground state at $5/2$ was spin-unpolarized because of this which largely ruled out non-Abelian physics and the Pfaffian state, see Section “Surface acoustic waves, geometric resonance transport, light scattering, and Knight shift: Spin polarization”. However, Morf (1998)’s seminal work changed the paradigm by providing substantial support for the Pfaffian description of $5/2$.

Morf (1998) studied the pure Coulomb interaction via exact diagonalization in the spherical geometry for up to $N = 18$ electrons. As noted above, in the spherical geometry for electrons half-filling the second LL (the lowest spin-up and spin-down lowest LLs are taken to be fully occupied and inert) the relationship between Q and N for electrons in the second LL is $2Q = 2N - S$. In the limit of $Q \rightarrow \infty$ the filling factor is $1/2$ in the second LL no matter the value of S . The Pfaffian has $S = 3$ but there is no a priori reason to fix S in exact diagonalization.¹ However, any FQH candidate state has to be a rotationally invariant state with $L = 0$ (uniform density) and a finite energy gap.

Morf (1998) showed three important things: fully spin polarized states had lower ground state energy than spin-unpolarized states, $S = 3$ had $L = 0$ ground states for all even N compared to other S , the state for $S = 3$ was found to have a finite energy gap in the thermodynamic limit (Fig. 5, top). In addition, it was shown that the wave function overlap between the exact ground state for $S = 3$ and the Pfaffian state was substantial (60–80%) and could be made nearly unity by increasing the $V_1^{(1)}$ pseudopotential by 10% compared to the bare value—the energy gap was also found to be maximum at this value of increased $V_1^{(1)}$.

A technically important point for numerical calculations is that H_3 , which in the spherical geometry is written as

$$H_3 = \sum_{i < j < k} \hat{P}_{ijk}(3Q - 3), \quad (21)$$

Fig. 5 (Top) Morf (1998) found the energy gap for the Pfaffian shift at $S = 3$ to be finite in the thermodynamic limit and that the low energy dispersion for fixed number of particles N displays a roton mode at finite wave vector (not shown). (Bottom) The ground state energy, obtained using density-matrix-renormalization-group techniques by Feiguin et al. (2009) for Eq. (1) in the second LL in the spherical geometry, versus inverse particle number. The thermodynamic limit is obtained for $1/N \rightarrow 0$. DMRG was able to study the largest systems to date and found the fully spin-polarized $P = 1$ ground state at the Pfaffian shift of $S = 3$ to be lower in energy than partially polarized states $P \neq 1$. This result significantly bolstered earlier results of Morf (1998). The figures are taken from Morf RH (1998) Transition from quantum Hall to compressible states in the second Landau level: New light on the $\nu = 5/2$ enigma. *Physical Review Letters* 80: 1505–1508. <https://doi.org/10.1103/PhysRevLett.80.1505> and Feiguin AE, Rezayi E, Yang K, Nayak C, and Das Sarma S (2009) Spin polarization of the $\nu = 5/2$ quantum Hall state. *Physical Review B* 79: 115322. <https://doi.org/10.1103/PhysRevB.79.115322> with permission.

¹We note a technical point in numerical studies on the sphere. From Table 3 some of the shifts for various candidate states can be up to $S = 9$. These large shifts are complicated to analyze due to an effect called “aliasing” where an instance of $(2Q, N)$ in Eq. (20) can correspond to a different filling factor ν' and a different shift S' or perhaps an excited state of an unrelated FQH state at yet another filling factor, see discussion in Morf et al. (2002).

where $\hat{P}_{ijk}$ is a projection operator onto electron triplets with maximum angular momentum $L = 3Q - 3$, can be solved to produce the Pfaffian state exactly in the second quantized representation. This greatly facilitates overlap calculations since the inner product can be calculated as a sum rather than a multi-dimensional integral. Furthermore, the energy spectrum of H_3 provides a model spectrum of a paired FQH state in a half-filled LL.

Note that Morf (1998) did not study the anti-Pfaffian with $S = -1$, which was not known at the time. Due to the particle-hole symmetry of the Hamiltonian, all the results would be identical² to $S = 3$ anyway.

The spin-polarization of the Coulomb interaction in the second LL is a numerically taxing problem to study, i.e., the Fock space is formidably large. While Morf (1998)'s early calculations strongly supported a spin-polarized ground state for $S = 3$, this result was more firmly established via DMRG for up to $N = 26$ particle Feiguin et al. (2008, 2009) (see Fig. 5, bottom). There is little numerical doubt that the FQH ground state at $5/2$ is fully (or mostly) spin-polarized; see Biddle et al. (2013), Park et al. (1998) and Dimov et al. (2008) for more support using variational Monte Carlo techniques and Ginzburg-Landau theory, respectively. It is noteworthy that spin-polarization is maintained under realistic effects such as LL mixing and finite thickness of the quantum well Rezayi and Simon (2011).

Excitation gaps

There are several energy gaps relevant for the FQH effect at the $5/2$ state. The transport gap, the “neutral” gap, and the neutral fermion gap. The thermodynamic stability of the FQH effect at $5/2$ depends on all three.

Transport gap

The transport gap is the energy of a far separated quasiparticle/quasihole pair and is the gap experimentally measured by examining the longitudinal resistance; see Section “Early experiments and evidence for/against non-Abelian states”. Here we discuss the transport gap calculated via exact diagonalization in the spherical geometry. The transport gap can be calculated two ways. One is to calculate the ground state energy for systems with $2Q = 2N - 3$ and $2Q = 2N - 3 \pm 1$, the ± 1 creates a two quasihole state or two quasiparticle state, respectively, with charges $\pm e/4$. The transport gap is the average of these excitation energies. Another method is to consider the low-energy dispersion at fixed N and take the gap between the lowest energy state for $L = N/2$ (for a paired state like the Moore-Read Pfaffian or $L = N$ for an unpaired state) and the $L = 0$ ground state.

Both of these methods for obtaining the transport gap are approximately the same. Morf (1998) found this transport gap to be approximately $0.05 e^2/\epsilon\ell_0$ —the $\nu = 1/3$ Coulomb state in the lowest LL has a gap of about $0.1 e^2/\epsilon\ell_0$ for comparison Jain (2007). The gap calculations of Morf (1998) have been bolstered over the years, see Feiguin et al. (2008), Morf et al. (2002), Pakrouski et al. (2015). We note that Park and Jain (2000) used the GMP approximation to calculate the energy gap dispersion for the Pfaffian state finding similar results to Morf (1998) both qualitatively and quantitatively.

Neutral gap

The “neutral” gap is defined as the difference between the $L = 0$ ground state energy and the energy of the first excited state for any L . Morf (1998) calculated the neutral gap at $2Q = 2N - 3$ and found it to be approximately $0.02 e^2/\epsilon\ell_0$. This gap is thought to be accessible experimentally via photoluminescence spectroscopy; see Section “Light scattering”. In general, the neutral gap is smaller than, but of the same order of magnitude as, the transport gap.

Neutral fermion gap

The Pfaffian supports a neutral fermion excitation mode which is the gap for the Bogoliubov-de Gennes quasiparticles in the p -wave superconductor analogy for the Pfaffian state Bonderson et al. (2011), Greiter et al. (1991, 1992), Möller et al. (2011), Moore and Read (1991), Read and Green (2000)—this is not the “neutral” gap discussed above. This mode technically can be calculated in the spherical geometry by studying a system at $S = 3$ but for odd particle numbered systems instead of even required for pairing. Bonderson et al. (2011), (Sreejith et al., 2011), Hutzler et al. (2019), Möller et al. (2011) calculated the neutral fermion mode for the Pfaffian state and for the ground state of the second LL Hamiltonian corresponding to $5/2$, see Fig. 6. Similar to the overlap and gap calculations of Morf (1998), increasing the $V_1^{(1)}$ Haldane pseudopotential by approximately 10% produced a result more in line with the Pfaffian expectation.

Realistic effects on energy gaps

Realistic effects such as LL mixing and/or finite thickness of the quantum well have been shown to generally reduce the size of the energy gaps by up to 50% Dean et al. (2008b), Luo et al. (2021), Morf et al. (2002), Pakrouski et al. (2015), Peterson et al. (2008a, 2008b). However, theoretical calculations still overestimate the experimentally measured energy gaps; see Section “Early experiments and evidence for/against non-Abelian states” below.

²For a particle-hole symmetric Hamiltonian in the spherical geometry in a half-filled LL, all spectra for S are identical to those with $S \rightarrow 2 - S$. Hence, the Pfaffian spectra for $S = 3$ is identical to the anti-Pfaffian spectra for $S = -1$.

Fig. 6 Neutral fermion mode versus wave vector k in units of the magnetic length calculated using exact diagonalization in the spherical geometry by Möller et al. (2011). The right panel shows the mode for the Pfaffian state (in this work they denote the second LL Coulomb Hamiltonian H as $\mathcal{H}_C(LL_1)$ and H_3 as $\mathcal{H}_P$), whereas the left panel is the neutral fermion mode for the $n = 1$ Coulomb Hamiltonian. Increasing $V_1^{(1)}$ a little bit produces a mode closer qualitatively to that of the pure Pfaffian state, similar to overlaps and gaps found by Morf (1998). Note that Möller et al. (2011) denote λ as the magnetic length ℓ_0 . The figure is taken from Möller G, Wójs A, and Cooper NR (2011) Neutral fermion excitations in the Moore-Read state at filling factor $\nu = 5/2$. *Physical Review Letters* 107: 036803. <https://doi.org/10.1103/PhysRevLett.107.036803> with permission.

Evidence for pairing

An important physical aspect of the Pfaffian state is that the composite fermions form pairs analogous to a p -wave superconductor. Scarola et al. (2000a) used Monte Carlo with the composite fermion wavefunctions in the spherical geometry, showing that the residual interaction between the composite fermions in the second LL is attractive. This attractive interaction is not found for composite fermions in the half-filled lowest LL, see Fig. 7.

Lu et al. (2010) showed an even-odd effect in the ground state energy per particle for the second LL Coulomb Hamiltonian indicative of pairing. This effect was absent in the lowest LL and instead was qualitatively similar to the “shell” structure expected of a composite fermion Fermi sea. In addition, Lu et al. (2010) calculated a “superconducting order parameter”, $\langle c_s^\dagger(\mathbf{r})c_s^\dagger(0) \rangle$, where the

Fig. 7 (Left) The interaction energy for pairs of electrons ($B = 0$) and composite fermions ($B^* = 0$) in the lowest and second LL, respectively, versus angular momentum L , i.e., the pseudopotentials in the spherical geometry for $N = 27$ particles. Increasing L corresponds to increasing inter-particle separation when in a single LL. The short range composite fermion pseudopotentials are negative for $5/2$ but not $1/2$ where they are similar to those for electrons at $B = 0$. (Right) The binding energy Δ for a composite fermion pair in the second Landau level, compared to the lowest Landau level, extrapolates to a negative value as $1/N \rightarrow 0$ indicating a pairing instability in the $L = 1$ channel. Figures are taken from Scarola VW, Park K, and Jain JK (2000a) Cooper instability of composite fermions. *Nature (London)* 406: 863–865. <http://www.nature.com/nature/journal/v406/n6798/abs/406863a0.html> with permission.

creation operators $c_*^\dagger$ are composite fermion creation operators since they are the objects that pair in the Pfaffian state compared to electrons, see Fig. 3 in Lu et al. (2010). In addition to the above calculations, a small increase in the pair correlation function of the Pfaffian state, calculated via Monte Carlo, for small distances has been interpreted as evidence for real space pairing Park et al. (1998).

The relative stability of the Pfaffian phase and further evidence for pairing was demonstrated by Möller and Simon (2008), who considered a larger class of wave functions of the Pfaffian form, i.e.,

$$\Psi_{\text{CF-pairing}}(z_i) = J^2 \text{Pf}[g(z_i - z_j)] \quad (22)$$

where $g(z_i - z_j)$ is an antisymmetric pairing function for the composite fermions. The Pfaffian state has $g(z_i - z_j) = 1/(z_i - z_j)$, see Eq. (7). By varying the form of the interaction potential and using the pairing function as a variational parameter, it was shown through the calculation of wave function overlaps in the spherical geometry between $\Psi_{\text{CF-pairing}}$ and the exact ground state that the pairing is maintained under realistic conditions, and the ground state remains in the Pfaffian phase. A similar conclusion was more recently obtained in the torus geometry by Sharma et al. (2021).

Topological properties

Any candidate for the FQH state at $5/2$ must have an energy gap. There is also a consensus that some sort of pairing must be involved. However, the Pfaffian/anti-Pfaffian state has specific signatures related to yet another important property: non-Abelian topological order.

Topological shift

The shift S in the spherical geometry is a topological quantum number related to the topological order of the FQH state. The shift arises due to the orbital motion and the curvature of the sphere Wen and Niu (1990). Various candidate FQH states have an associated shift when represented in the spherical geometry. Incidentally the shift is related to the Hall viscosity Read (2009). As discussed above Morf (1998) found in the absence of LL mixing effects that $S = 3$ was rotationally invariant for all even N and had a finite energy gap. This is not necessarily true for other S .

The torus geometry does not have a shift. However, the so-called infinite-DMRG calculations done on an infinite cylinder can cleverly extract the shift from the quantum entanglement data of the ground state as the leading term of a theoretical object called the “momentum polarization” Tu et al. (2013), Zaletel et al. (2013, 2015).

Ground state degeneracy

In the torus geometry, the Pfaffian state displays an exact threefold ground state degeneracy at unique values of pseudomomenta. Note that we have factored out the (trivial) twofold center-of-mass degeneracy from the filling factor. This degeneracy can be understood analytically, see Greiter et al. (1992), and shows up numerically as well. Thus, if the second LL Coulomb interaction Hamiltonian is in the Pfaffian phase it should show this threefold (quasi)degeneracy. Peterson et al. (2008a, 2008b, 2010), Rezayi (2017), Wang et al. (2009) all found the threefold quasi-degeneracy manifest for the $5/2$ system. In fact, Peterson et al. (2008a, 2008b) found that the realistic effect of finite thickness of the quantum well enhanced the degeneracy compared to the pure second LL Coulomb interaction.

Wave function overlaps

The numerical wave function overlap between the Pfaffian state and second LL Coulomb ground state was calculated by Morf (1998) and found to be nearly 80% and could be made nearly unity by increasing the short-range Haldane pseudopotential. We note that the interpretation of overlap calculations, while used widely in the study of FQH states, are subtle. Overlaps are necessarily calculated for finite size systems and vanish in the thermodynamic limit trivially. Thus, a high overlap should not be taken as evidence of the existence of a phase in isolation. Nonetheless, high overlaps between the exact ground state of second LL Coulomb interaction have been routinely calculated and have been shown to increase with moderate finite thickness of the quantum well before eventually decreasing at very wide quantum wells (Jeong and Park, 2015; Morf, 1998; Pakrouski et al., 2015; Papić et al., 2009; Peterson et al., 2008a,b; Rezayi, 2017; Rezayi and Simon, 2011; Tylan-Tyler and Lyanda-Geller, 2015; Wang et al., 2017).

Entanglement entropy and spectra

The overlap is not universal and vanishes in the thermodynamic limit. The entanglement entropy and spectrum provide a more universal signature. A wave function’s entanglement entropy is calculated by dividing the system into two subsystems A and B , in orbital space,³ and constructing the reduced density matrix ρ_A by taking a partial trace of all the degrees of freedom in the B subsystem, or vice-versa Srednicki (1993). The entanglement entropy is then the von Neumann entropy $S_E = -\text{Tr}[\rho_A \ln \rho_A]$ of ρ_A . For gapped ground states, S_E can be shown to generically scale with the length of the boundary between the two subsystems

³The division into subsystems can also be done in real space, see Sterdyniak et al. (2012). We consider only orbital cuts here.

Srednicki (1993). If a state has topological order, S_E will show a reduction by a universal constant, i.e., for a topological state the entanglement entropy is expected to obey

$$S_E = \alpha L - \gamma + \mathcal{O}(1/L) \quad (23)$$

where L is the length of the boundary, α is a system dependent non-universal constant, and γ is the so-called topological entanglement entropy Kitaev and Preskill (2006), Levin and Wen (2006). For a topologically ordered state $\gamma = \ln \mathcal{D}$ where $\mathcal{D}$ is the total quantum dimension of the theory, see Nayak et al. (2008). For the Pfaffian, $\gamma = \ln \sqrt{8}$ Dong et al. (2008), Fendley et al. (2007), Moore and Read (1991), Zozulya et al. (2007).

Consistent with energy gaps and overlaps, Friedman and Levine (2008) and Biddle et al. (2011) found that γ for ground state of the half-filled second LL Hamiltonian was consistent with the value for the Pfaffian state when finite thickness of the quantum well was included, see Fig. 3 in that work.

It turns out there is far more information in ρ_A than the entanglement entropy. Li and Haldane (2008) investigated the eigenvalues of ρ_A and defined corresponding entanglement “energies” ξ_n whose spectrum is called entanglement spectrum. The entanglement spectrum can be used as a universal “fingerprint” to identify the topological order of a wave function. The low-lying levels are related quantitatively and qualitatively to the related CFT and its corresponding edge theory—the orbital cut is thought to create an edge of sorts and the edge excitations can be studied. Fig. 8 shows the entanglement spectra calculated by Li and Haldane (2008) for the ground state of the half-filled second LL for a system with $N = 16$ electrons in the spherical geometry. The inset shows the entanglement spectra for the Pfaffian wave function. For the Coulomb state there are several low-lying levels that match those of the Pfaffian and there is a so-called “topological entanglement gap” to non-universal levels protecting the topological properties.

The low-lying entanglement spectrum for the $5/2$ system is maintained when finite thickness effects are included in addition to LL mixing effects (Section “Competing phases and Landau level mixing”).

Edge velocities

While the entanglement spectrum is used to investigate the edge excitations by proxy, Wan et al. (2006) utilized the disk geometry to study the edge excitations of the Pfaffian state and the second LL Coulomb state directly. Chiral edge excitations were identified and fractionally charged excitations were consistent with the Pfaffian description. Additionally, the velocities for the fermionic and bosonic excitation branches v_b and v_f respectively, were found to satisfy $v_b \gg v_f$. In a follow up work, Wan et al. (2008) mixed in the three-body H_3 term perturbatively to the analysis (similar to LL mixing discussed below) and suggested that a smooth edge confinement potential might favor the anti-Pfaffian state while a sharp edge favors the Pfaffian. As mentioned above, finite size effects arise more readily in the disk geometry and this work required particular care to choose a proper confining potential.

In contrast to edge studies in the disk geometry, Soulé et al. (2013) studied edge modes of the Pfaffian state (compared to the second LL Coulomb ground state) in a QPC-type geometry using an open cylinder. With a combination of exact diagonalization, using H_3 to generate the Pfaffian state exactly, and Monte Carlo, it was found that $v_b \approx v_f$.

Non-Abelian quasiparticles

Perhaps the most interesting aspect of non-Abelian FQH states is the braiding statistics of the excitations and their non-Abelian nature Moore and Read (1991), Nayak and Wilczek (1996), Prodan and Haldane (2009), Read and Rezayi (1996). Within the context of CFTs the non-Abelian braiding statistics are well-established as discussed above in Section “Theoretical background”. In the spherical geometry the Pfaffian Hamiltonian in Eq. (19) produces a zero-energy 2^{n-1} degenerate manifold of states from

Fig. 8 The low-lying entanglement spectra ξ for the ground state of the half-filled second LL Coulomb interaction Hamiltonian for $N = 16$ electrons in the spherical geometry as a function of z -component of total angular momentum L_z^A in the A partition. The inset shows low-lying entanglement spectra for the Pfaffian state. The low-lying levels of both are in close correspondence and match the expectations from CFT for the Pfaffian. $P[0|0]$ corresponds to a particular orbital cut explained in detail by Li and Haldane (2008). The figure is taken from Li H and Haldane FDM (2008) Entanglement spectrum as a generalization of entanglement entropy: Identification of topological order in non-abelian fractional quantum Hall effect states. *Physical Review Letters* 101: 010504. <https://doi.org/10.1103/PhysRevLett.101.010504> with permission.

$2n$ quasiholes, separated from the continuum by an energy gap, when exactly diagonalized at $2Q = 2N - 3 + n$. The degeneracy 2^{n-1} is only obtained in the limit of $N \gg n$ and finite size effects produce more complicated degeneracies given in Table I of Read and Rezayi (1996)—an example of the non-Abelian zero-energy quasihole manifold is shown Fig. 3 of the same work for a system with $N = 10$ electrons. These quasihole excitations are analogous to the vortex excitations in the p -wave superconductor analogy of the Pfaffian state. Monte Carlo calculations were performed by Tserkovnyak and Simon (2003) confirming the CFT predictions of the Pfaffian quasihole wave functions Nayak and Wilczek (1996). Using the so-called bipartite composite fermion theory, (Sreejith et al., 2011a,b) constructed ansatz states for the non-Abelian quasiparticle excitations that accurately represent the non-abelian excitations of Eq. (19) and possibly are adiabatically connected to the low-energy states of the second LL Coulomb Hamiltonian.

However, a fair amount of numerical controversy continues regarding the question of whether non-Abelian excitations are manifest in a system with a realistic interaction appropriate for the FQH effect at $5/2$. Generally, the Coulomb interaction, even when realistic effects such as LL mixing and finite thickness are included, does not show a zero-energy manifold of non-Abelian quasihole states separated from the continuum by an energy gap. Instead the quasihole degeneracy is strongly broken and the energy gap is not clearly discerned Peterson et al. (2008c), Töke and Jain (2006), Wójs et al. (2010). Recently, Hutzl et al. (2019) showed that the zero-energy quasihole manifold is adiabatically connected to a degeneracy-broken set of states of a two-body Hamiltonian related more closely to the second LL Coulomb Hamiltonian than the three-body Hamiltonian of Eq. (19). Thus, it is possible that the broken quasihole degeneracy generally observed in two-body interacting systems is a consequence of finite-size effects and mutual quasihole interactions Nayak et al. (2008).

Finally, a recent parton wave function describing a half-filled FQH state, called the $\bar{2}\bar{2}111$ state was constructed based on the original idea in Jain (1989b). This wave function is constructed and analyzed in real space, via Monte Carlo for example, and was shown to be in the same phase as the anti-Pfaffian via an analysis of its entanglement spectra, wave function overlap, and pair correlation function Balram et al. (2018a). Since the anti-Pfaffian does not have a simple real space expression similar to Eq. (6) for the Pfaffian, the $\bar{2}\bar{2}111$ state is a particularly convenient representation. Beyond the convenience of the $\bar{2}\bar{2}111$ representation of the anti-Pfaffian, the parton theory of the half-filled second LL suggests a unique hierarchy of expected FQH states. In particular, the sequence of states from $\nu = 2 + 2/3$ to $2 + 1/2$ and $2 + 6/13$ discussed as possibly exotic in experiments Kumar et al. (2010). The $2 + 6/13$ state, which is topologically equivalent to the hierarchy state of Levin and Halperin (2009), is unexpected from weakly interacting composite fermion theory without the more robust observations of states at $\nu = 2 + n/(2n + 1)$ for $1 \leq n \leq 5$, see (Balram, 2021; Balram et al., 2018b, 2019). In fact, recent experimental work by Huang et al. (2022) in bilayer graphene used this method to investigate whether various half-filled FQH states arose from the anti-Pfaffian or the Pfaffian.

Adiabatic continuity

Historically, an important piece of numerical evidence supporting the Laughlin description of the FQH effect at $\nu = 1/3$ was that the Laughlin state was adiabatically connected to the Coulomb ground state. In this case the logic is straightforward. The Laughlin state for $1/3$ is the exact ground state of Eq. (1) for which only $V_{1,\text{two-body}}^{(0)} \neq 0$ while all others are set to zero, the so-called hard-core potential. To show adiabatic continuity between the lowest LL Coulomb ground state and the Laughlin state, one calculates the energy spectrum for the Coulomb Hamiltonian and then “adiabatically” reduces all Haldane pseudopotentials other than $V_{1,\text{two-body}}^{(0)}$ to zero. If the energy gap remains finite throughout this process then the ground states for the “hardcore” potential and the lowest LL Coulomb Hamiltonian are equivalent.

For the FQH effect at $5/2$, demonstrating adiabatic continuity is more complicated. Complications arise because H_3 (producing the Pfaffian) is a three-body interaction that is (i) artificial and (ii) breaks particle-hole symmetry. Nonetheless, one can construct a Hamiltonian that interpolates between the second LL Coulomb interaction and H_3 , i.e., $H(\alpha) = (1-\alpha)H + \alpha H_3$. In Storni et al. (2010) [and a related calculation in Hutzl et al., 2019] it was shown that for the second LL Coulomb interaction the energy gap remained open as α was tuned from zero to one showing adiabatic continuity between the Pfaffian state and the ground state for $5/2$, for finite sized systems. Interestingly, adiabatic continuity was not obtained for the lowest LL Coulomb interaction showing second LL physics is crucial for the formation of the Pfaffian state.

Competing phases and Landau level mixing

So far we have discussed a preponderance of evidence showing that the Pfaffian (and anti-Pfaffian) states are viable states to describe the FQH effect at $5/2$ even in realistic systems with finite quantum well thickness. However, small changes in Hamiltonian parameters have demonstrated that transitions to other competing states are possible Peterson et al. (2008a, 2008b), Rezayi (2017), Wójs et al. (2010). For example, Rezayi (2017) performed exact diagonalization on both the sphere and torus and found a first-order quantum phase transition between the Pfaffian state and a compressible stripe (anisotropic) phase. Interestingly, the pure second LL Coulomb Hamiltonian was found to be barely on the compressible side of the phase transition but increasing the finite width of the quantum well was shown to drive the system into the Pfaffian phase.

Of particular interest are perturbations that can break the degeneracy between the Pfaffian and anti-Pfaffian. The system for the particle-hole symmetric second LL Coulomb Hamiltonian is right at the cusp of a (first-order) transition between these degenerate states without a particle-hole symmetry breaking term Peterson et al. (2008c), Wang et al. (2017). Realistic effects such as finite thickness soften the interaction generally, i.e., the Haldane pseudopotentials are reduced. LL mixing, however, not only softens the interaction, it also explicitly breaks particle-hole symmetry Bishara and Nayak (2009). Since the Pfaffian and anti-Pfaffian are related via particle-hole conjugation, LL mixing is an important effect.

LL mixing can be taken into account in essentially two ways. One way is to expand the Fock space to include higher and lower LLs, i.e., allow basis states with partially filled lower and higher LLs instead of projecting all the physics to the half-filled second LL. This increased Fock space must still be truncated to a finite size in order to do any calculations. Papić et al. (2012), Rezayi and Simon (2011), Zaletel et al. (2015) all analyzed the 5/2 FQH state using various non-perturbative methods that are not controlled or exact in any limit.

In contrast, Peterson and Nayak (2013), Simon and Rezayi (2013), Sodemann and MacDonald (2013), Wooten et al. (2013) constructed an effective Hamiltonian that included LL mixing perturbatively to lowest order in the LL mixing parameter κ . Hence, this approximation is exact for $\kappa \rightarrow 0$. Further, Peterson and Nayak (2013) constructed an effective Hamiltonian that included LL mixing and finite thickness. This latter effect is subtle since it requires LL and quantum well sub-band mixing. The form of the effective Hamiltonian is

$$H(w, \kappa) = \sum_m \left[V_{m,\text{two-body}}^{(1)}(w) + \kappa \delta V_{m,\text{two-body}}^{(1)}(w) \right] \sum_{i < j} \hat{P}_{ij}(m) + \kappa \sum_m \tilde{V}_{m,\text{three-body}}^{(1)}(w) \sum_{i < j < k} \hat{P}_{ijk}(m) \quad (24)$$

where $V_{m,\text{two-body}}^{(1)}(w)$ is the bare finite thickness dependent two-body Haldane pseudopotential, $\delta V_{m,\text{two-body}}^{(1)}(w)$ is its perturbative correction due to LL and sub-band mixing, and $\tilde{V}_{m,\text{three-body}}^{(1)}(w)$ is the emergent particle-hole symmetry breaking three-body pseudopotential Simon et al. (2007).

Perturbative LL mixing treatment I

Wójs et al. (2010) were the first to numerically investigate the particle-hole symmetry breaking effective LL mixing Hamiltonian constructed by Bishara and Nayak (2009). Assuming spin-polarized electrons, Wójs et al. (2010) studied the ground state and low-energy excitations of the realistic second LL Hamiltonian as a function of κ at $S = 3$ (for the Pfaffian) and $S = -1$ (anti-Pfaffian). It was found, primarily through wave function overlaps, that the Pfaffian and its low-energy excitations were favored compared to the anti-Pfaffian. We note, however, that the two-body pseudopotentials of the effective LL Hamiltonian calculated by Bishara and Nayak (2009) were incorrect due to a subtle normal-ordering error in the perturbation theory—this error was corrected by Peterson and Nayak (2013), Sodemann and MacDonald (2013).

Non-perturbative LL mixing treatment I

Rezayi and Simon (2011) did an exact diagonalization study in the torus geometry using a truncated Fock space that included LL mixing non-perturbatively. In particular, it was shown by comparing the size of the wave function overlap between the exact ground state and the Pfaffian or anti-Pfaffian that a model that included three LLs in the truncated Fock space, the Pfaffian was preferred. However, increasing the Fock space to include four and five LLs, the anti-Pfaffian was preferred.

We note that Wójs and Quinn (2006) studied the 5/2 FQH effect under LL mixing using a truncated Fock space similar to Rezayi and Simon (2011) finding chiefly that the energy gap is strongly reduced. However, they did not discuss the anti-Pfaffian since it had not been proposed yet.

Perturbative LL mixing treatment II

The effective Hamiltonian in Eq. (24) was analyzed via exact diagonalization in the spherical and toroidal geometry by Pakrouski et al. (2015). It is noteworthy that only the lowest $m \leq 8$ emergent three-body pseudopotentials $\tilde{V}_{m,\text{three-body}}^{(1)}$ were taken into account by Pakrouski et al. (2015)—above $m = 8$ some of the three-body terms become multi-valued and it is non-trivial to consider these types of terms in calculations. However, the $\tilde{V}_{m,\text{three-body}}^{(1)}$ decrease in value for increasing m and presumably have little effect, see Section “Perturbative LL mixing treatment III” below to revisit this aspect. By analyzing wave function overlaps, entanglement spectra, energy gaps, and an order parameter used to determine particle-hole symmetry breaking, it was found that the Pfaffian state edges out the anti-Pfaffian throughout parameter space. The approximate quantum phase diagram calculated by Pakrouski et al. (2015) is shown in Fig. 9. The stability of the Pfaffian phase was measured via the “neutral” energy gap. Sharp peaks in the entanglement entropy indicate phase transitions to a compressible state for $\kappa > 0.7-1$ (depending on w/ℓ_0). Between about $0.6 < \kappa < 0.7$ there was a hint of an intermediate FQH state. The entanglement spectra in this small window had low-lying levels with a slope opposite to the Pfaffian indicative of a state with edge modes opposite to the Pfaffian. However the entanglement and energy gaps were too small to reach a firm conclusion. Recent diagonalization and overlap calculations for $\kappa > 1$ suggest a reentrant anomalous quantized Hall state captured by Bose-Einstein condensates of composite bosons (Das et al., 2022).

Non-perturbative LL mixing treatment II

In contrast to the perturbative approach of Pakrouski et al. (2015), Zaletel et al. (2015) utilized infinite-DMRG to explore LL mixing effects within a truncated Fock space including up to five LLs. Starting at an experimentally relevant value of $\kappa = 1.38$, infinite-DMRG was performed on a truncated system, at zero quantum well thickness, with three LLs for decreasing values of κ toward the perturbative limit of $\kappa = 0$. The infinite-DMRG was performed by incorporating the matrix product form of either the Pfaffian or anti-Pfaffian on an infinite cylinder with a finite radius of approximately $20\ell_0$. By analyzing the energy splitting between the Pfaffian and anti-Pfaffian (see Fig. 10), they found the anti-Pfaffian phase dominates for all κ .

Fig. 9 Approximate quantum phase diagram for the FQH effect at $5/2$ calculated by Pakrouski et al. (2015) as a function of quantum well width $w\ell_0$ and LL mixing parameter κ in the spherical geometry for a system of $N = 18$ electrons. The area left of the lines with black circles and diamonds corresponds to the Pfaffian state as determined by wave function overlap, entanglement spectrum, and a particle-hole symmetry breaking order parameter. The color indicates the strength of the “neutral” energy gap which indicates the stability of the phase. The magnetic field values in Tesla are shown on the upper ordinate ($\kappa \propto 1/\sqrt{B}$). The lines with the black circles and diamonds indicate peaks in the entanglement entropy marking phase transitions. The area to the right of the black diamonds is a non-FQH state. The small area in-between the circles and diamonds around $0.6 < \kappa < 0.7$ has a possible FQH ground state with edge modes moving opposite to the Pfaffian. The figure is taken from Pakrouski K, Peterson MR, Jolicœur T, Scarola VW, Nayak C, and Troyer M (2015) Phase diagram of the $\nu = 5/2$ fractional quantum Hall effect: Effects of Landau-level mixing and nonzero width. *Physical Review X* 5: 021004. <https://doi.org/10.1103/PhysRevX.5.021004> with permission.

Fig. 10 Energy estimate from Zaletel et al. (2015) of the splitting between the Pfaffian and anti-Pfaffian states calculated via DMRG using a truncated Fock space simulating LL mixing as a function of κ . The positive value indicates the anti-Pfaffian is preferred from the experimentally relevant value of κ toward zero. The figure is taken from Zaletel MP, Mong RSK, Pollmann F, and Rezayi EH (2015) Infinite density matrix renormalization group for multicomponent quantum Hall systems. *Physical Review B* 91: 045115. <https://doi.org/10.1103/PhysRevB.91.045115> with permission.

Perturbative LL mixing treatment III

Motivated by the contrasting results of Pakrouski et al. (2015) and Zaletel et al. (2015), Rezayi (2017) re-investigated the perturbative approach for zero quantum well width using the torus and spherical geometries for $N = 15$ and 16 electron systems. The torus geometry was utilized to directly compare the Pfaffian and anti-Pfaffian since there is no shift. The main difference between Rezayi (2017) and Pakrouski et al. (2015) was the inclusion of an approximate⁴ $m = 9$ three-body LL mixing pseudopotential term in Eq. (24). As noted above, most of the emergent three-body pseudopotentials due to LL mixing above $m = 8$ are

⁴The multi-component $m = 9$ three-body term was diagonalized and the dominant term was taken as a single $m = 9$ term in Eq. (24).

multi-component. Including this term tipped the balance toward the anti-Pfaffian as determined by wave function overlaps between the exact ground state and the Pfaffian or anti-Pfaffian, in both geometries, up to $\kappa \sim 1$ where the overlap with the anti-Pfaffian vanishes (the Pfaffian overlap collapsed early around $\kappa \sim 0.6$). The “neutral” energy gap was also shown to be larger for the anti-Pfaffian compared to the Pfaffian state. This result was found to be rather stable to changes in the value of the $m = 9$ three-body pseudopotential. However it is unknown to what extent quantum well sub-band mixing might affect the result.

Perturbative LL mixing treatment IV

In Tylan-Tyler and Lyanda-Geller (2015) a phase diagram was calculated via a perturbative LL mixing treatment and edge effects were analyzed in the disk geometry. Here both LL mixing and the neutralizing background break the Pfaffian/anti-Pfaffian degeneracy. It was found there was a quantum phase transition from anti-Pfaffian to Pfaffian as κ is increased from zero, qualitatively in contrast to what was found by Pakrouski et al. (2015). In the thermodynamic limit, the boundary effect (from the trapping potential) that breaks the Pfaffian/anti-Pfaffian degeneracy is negligible as compared to the LL mixing effect from the bulk. Meanwhile, the actual sample does have a finite size where the edge effect is present, which may play a role in breaking this degeneracy.

Unexpected experimental results and the PH-Pfaffian

Numerical work has demonstrated that the Pfaffian/anti-Pfaffian is a strong candidate for a realistic model for the FQH effect at $5/2$ that includes finite thickness of the quantum well. LL mixing effects allow the possibility to determine whether a realistic system prefers the Pfaffian or anti-Pfaffian by explicitly breaking particle-hole symmetry. As discussed above, numerically that question remains unanswered as some calculations suggest the Pfaffian while others suggest the anti-Pfaffian. To some extent this question will have to be settled experimentally.

As discussed below in Section “Recent surprises and puzzles”, thermal conductance experiments by Banerjee et al. (2018) were recently performed and did not settle the Pfaffian/anti-Pfaffian question. Instead, these experiments were consistent with a candidate state that is particle-hole symmetric known as the PH-Pfaffian Zucker and Feldman (2016); see Eq. (14) above. In the spherical geometry, this state has a shift of $S = 1$ (the particle-hole symmetric point) and has scant numerical support at this time. The second LL Coulomb interaction does not consistently obtain a rotationally invariant state with $L = 0$ for all N at $2Q = 2N - 1$ with or without realistic effects of finite width and LL mixing. Furthermore, the overlap between the PH-Pfaffian and the exact second LL Coulomb ground state was shown by Balram et al. (2018a) to be nearly zero. On the other hand, the overlap with the lowest-lying $L = 0$ LLL Coulomb ground state is rather high leading Balram et al. (2018a) to speculate that the PH-Pfaffian is a critical state corresponding to a particle-hole symmetric pairing instability of the composite fermion Fermi sea [see also the theoretical discussion in Milovanović, 2017]. These results are consistent with those of Geraedts et al. (2016), Mishmash et al. (2018), Pakrouski (2021), Rezayi et al. (2021), Yutushui and Mross (2020).

There are theoretical suggestions by Antonić et al. (2018), Milovanović and Djurdjević (2021), Milovanović et al. (2020), Zucker and Feldman (2016) that LL mixing and/or disorder are needed to stabilize the PH-Pfaffian state. Recently, Zhu and Sheng (2019) studied disorder-driven transitions in the $5/2$ FQH effect and found a transition from a pure Pfaffian/anti-Pfaffian phase, to an (unknown) intermediate phase, to a compressible composite fermion Fermi sea phase. The intermediate phase is consistent with either the PH-Pfaffian or the Pfaffian/anti-Pfaffian puddle state Lian and Wang et al. (2018), Mross et al. (2018), Wang et al. (2018), Zhu et al. (2020). Finally, Luo and Chakraborty (2017) found a positive gap (albeit less than the one for the Pfaffian shift of $S = 3$) for the PH-Pfaffian shift of $S = 1$ at finite κ via exact diagonalization on the sphere for $N = 10$ electrons. In this work they utilized yet another method of approximating LL mixing using an effective renormalized electron-electron interaction taking into account the polarizability of all the other Landau levels (random phase approximation) which preserves particle-hole symmetry.

Summary of numerical results

Extensive numerical work has been done since the discovery of the FQH effect at $\nu = 5/2$. The preponderance of evidence support the Pfaffian/anti-Pfaffian description for a realistic second LL Hamiltonian that takes into account the finite width of the quantum well. There is numerical support for the notion that the half-filled second LL Coulomb system is close to a first-order phase transition that breaks particle-hole symmetry between the Pfaffian and anti-Pfaffian. LL mixing is a realistic effect that explicitly breaks particle-hole symmetry. This effect has been incorporated into numerical studies in both the perturbative limit (exact as $\kappa \rightarrow 0$) and non-perturbative limit with mixed results. At the time of this writing, the (slim) majority of studies conclude the anti-Pfaffian is favored by LL mixing effects.

Meanwhile, thermal Hall conductance measurements at $\nu = 5/2$ yielded a result that was consistent with neither the Pfaffian nor anti-Pfaffian. Instead the result points toward either the PH-Pfaffian or disorder-induced Pfaffian/anti-Pfaffian puddle formation. The PH-Pfaffian has scant numerical support and disorder is notoriously difficult to include in numerical studies.

Early experiments and evidence for/against non-Abelian states

Theoretical developments in the quantum Hall effects walk hand-in-hand with experimental discovery and verification of hypotheses. Given the long list of possible candidates to describe the $5/2$ state (Table 3), it is natural to rely on experiments to distinguish these candidate theories. Of central interest is whether or not experiments can verify the non-Abelian nature of the $5/2$ state, and if so, which particular type. In this section, we summarize early experimental methods used to probe various properties of the $5/2$ state. We review these results in the context of verification or exclusion of assumptions underlying certain candidate states. The next section focuses on reviewing more recent results from thermal Hall conductance measurements specifically. See also prior reviews of experimental progress in Das Sarma and Pinczuk (1996), Heiblum and Feldman (2020), Jiang and Wan (2019), Lin et al. (2014), Schreiber and Cs  thy (2020), Willett et al. (2013).

Transport and optics: Bulk energy gap

Incompressibility in quantum Hall fluids requires a bulk energy gap. Larger gaps define more robust states and a vanishing of the gap defines phase boundaries in parameter space. Gaps at different momenta have acquired specific terminology.

The “transport gap” refers to the energy to create quasiparticle/quasihole pairs that are separated much further than their size, usually assumed to be directly related to gap inferred from the thermal activation transport measurements (in the following we refer to the activation gap measured in experiment as the “transport gap” to make connection with expectations from theory discussed in Section “Numerical methods and geometries”). The “neutral” bulk gap refers to the energy needed to create a quasiparticle-hole pair that are separated on the order of their size.

Numerical work shows that the quasiparticles at $\nu = 5/2$ can be as large as $\sim 10\ell_0$ Morf et al. (2002) and that the transport gap is expected to be much weaker than it is for filling factor $1/3$ (see Section “Overview of numerical results”). The small gap obtained from theory is consistent with measurements showing precise quantization of the $5/2$ plateau in the Hall resistance only at much lower temperatures than other fractions Pan et al. (1999b). The parameter dependence and size of these gaps offer a direct route to compare theory and experiment. Engineering a larger gap is an important goal for observing non-Abelian quasiparticles because many experiments become technically easier with large gaps.

Detailed transport measurements have been performed on the $5/2$ state since its discovery. The transport gap was typically found to be less than ≈ 600 mK although a recent breakthrough set a record at ≈ 820 mK Chung et al. (2021). As discussed below, the gap depends on sample parameters. The measured transport gap of the $5/2$ state is consistently found to be well below theory Choi et al. (2008), Dean et al. (2008a), Nuebler et al. (2010), Samkharadze et al. (2011) [as with the other FQH effect states Das Sarma and Pinczuk, 1996, Jain, 2007].

Several factors are known to lower the measured transport gap in comparison to the theoretical estimate of the charged gap. Finite thickness of the two-dimensional electron gas and LL mixing both soften the short range part of the Coulomb interaction and therefore lower the theoretical estimates Das Sarma and Pinczuk (1996), Jain (2007). But discrepancies still remain that are typically ascribed to disorder, which are seldom included in theoretical estimates of the gap Morf and d’Ambrumenil (2003), Wan et al. (2005).

Experimental parameters have shown a wide tun-ability of the transport gap. The following reviews experimental results showing the behavior of the transport gap at $5/2$ as various parameters are tuned. These include density, in-plane fields, quantum well width, disorder, and other aspects of sample design.

Density dependence

Electronic gating of the two-dimensional electron gas allows tuning of its density, ρ . At fixed filling, increasing the density requires a linear increase in the magnetic field since $\rho = \nu B/\phi_0$. Since the Coulomb energy scales as $1/\ell_0 \propto \sqrt{B}$, increasing the density would therefore nominally increase the strength of the $5/2$ energy gap in comparison to other energy scales, e.g., the temperature.

Early studies at $5/2$ showed a smooth dependence of the transport gap on density Pan et al. (2001). But the role of density has been more widely explored Liu et al. (2011a), Pan et al. (2014), Reichl et al. (2014), Samkharadze et al. (2017) to reveal more complex behavior. It has been found that the transport gap of the $5/2$ state is maximized at certain densities Liu et al. (2011a), Reichl et al. (2014) due to competing effects at high densities that include sub-band mixing. Furthermore, Samkharadze et al. (2017) found anomalous behavior in the transport gap and a possible topological phase transition at low densities, where LL mixing may play a role. At even lower densities, the gap was found to vanish in an apparent spin transition Pan et al. (2014) with later evidence for a nematic phase Samkharadze et al. (2016), Schreiber and Cs  thy (2020), Schreiber et al. (2018) (see Section “In-plane magnetic field and sample tilt impacts the bulk gap”). Competing phases therefore also play an important role in the density dependence of transport gap measurements at $5/2$.

Fig. 11 plots some of the measured transport gaps at $5/2$ reported in the literature (before 2014) as a function of the density of the two-dimensional electron gas. The data do not show a clear increasing trend with density. While competing phases play a role, other important effects such as impurity screening also significantly impact gap measurements.

Fig. 11 Transport gaps measured at filling $5/2$ normalized to Coulomb energy units ($E_{\text{Coul}} = e^2/\epsilon\ell_0$) as a function of density of the two-dimensional electron gas as reported for various heterostructures in the literature. The symbols correspond to the following references: (i) Reichl et al. (2014), (ii) Nuebler et al. (2010), (iii) Pan et al. (2008), (iv) Choi et al. (2008), (v) Miller et al. (2007), (vi) Eisenstein et al. (1990), (vii) Pan et al. (1999a), (viii) Pan et al. (2011), and (ix) Gamez and Muraki (2013). The figure is taken from Reichl C, Chen J, Baer S, Rössler C, Ihn T, Ensslin K, Dietsche W, and Wegscheider W (2014) Increasing the $\nu = 5/2$ gap energy: An analysis of MBE growth parameters. *New Journal of Physics* 16: 023014. <https://doi.org/10.1088/1367-2630/16/2/023014> with permission.

Disorder, mobility, and sample design

Disorder is believed to be responsible for a lowering of the transport gap. Disorder is typically parameterized by a constant shift Γ , where the measured transport gap is compared with $\Delta_A - \Gamma$ and Δ_A is the transport gap in the absence of disorder. The microscopic origin of Γ is not completely understood. Example scattering mechanisms include background impurities, interface roughness, alloys, or even phonons Ahn and Das Sarma (2022). Generally speaking, disorder which is in some way biased to lower the energy of spatially non-uniform excitations in comparison to otherwise uniform FQH ground states, would tend to lower the energy gap.

Mobility is often used as a proxy for sample quality because increases in zero-field sample mobility tend to, on average, increase the measured transport gap at $5/2$ Choi et al. (2008), Chung et al. (2021), Dean et al. (2008b), Deng et al. (2014), Pan et al. (2011), Qian et al. (2017b), Reichl et al. (2014), Samkharadze et al. (2011, 2017), Shingla et al. (2018). But it is well known that the interplay of disorder, length scales, screening, and temperature leaves the zero-field sample mobility as only rather indirectly related to sample quality at it pertains to $5/2$ Ahn and Das Sarma (2022), Das Sarma and Hwang (2014a, 2014b). This is consistent with a recent comparison between low field electron quantum lifetime measurements and $5/2$ transport gaps which found a lack of correlation between these two quantities Qian et al. (2017a). The energy gap of the $5/2$ state, however, was found to depend monotonically on the mobility in the regime in which only one scattering mechanism dominates, in this case alloy scattering Deng et al. (2014), Kleinbaum et al. (2020).

Screening of sample dopants and impurities can help increase the $5/2$ transport gap. Fig. 11 shows a general increase in the gap with density (as nominally expected) but there is not a clear trend because many other factors impact the gap. For example, moving dopants far from the two-dimensional electron gas was reported to increase the $5/2$ gap Reichl et al. (2014). Also, a nontrivial dependence was found depending upon the range of disorder in the type of sample used Pan et al. (2011). Furthermore, the FQH effect was observed at $5/2$ at rather low mobility after illumination Gamez and Muraki (2013). These findings underscore the complex role of impurity screening on sample quality.

The non-trivial interplay of impurities and other parameters such as sub-band splitting led to work on the role of sample design itself to possibly engineer higher $5/2$ transport gaps. It was found that samples designed to lower impurity concentrations while allowing a wide tuning of the electron density maximizes the $5/2$ gap Chung et al. (2021), Liu et al. (2011a), Pan et al. (2011), Reichl et al. (2014), Watson et al. (2015). Furthermore, while it is usually expected that widening the width of quantum wells lowers the transport gap (due to a softening of the short range part of the effective Coulomb interaction; see Section “Overview of numerical results”), some experiments do show that widening the well width can increase the gap Xia et al. (2010), consistent with numerical simulations incorporating the trade off in competing phases Peterson (2012).

A recent breakthrough increased the $5/2$ gap in GaAs-based quantum wells to a record 820 mK Chung et al. (2021). This significant (30%) improvement over the previous record Choi et al. (2008), Qian et al. (2017b) was achieved by reducing background impurities. A recent analysis by Ahn and Das Sarma (2022) points out that the new record brings the measured transport gap to within 40% of an ideal theoretical gap that includes only finite thickness (see Section “Numerical methods and geometries” for a discussion of finite thickness in numerics).

Confinement, pressure, and in-plane electric fields have also been explored as sample design parameters. Survival of the $5/2$ state under lateral confinement in quantum point contacts (QPCs) is important for edge tunneling and braiding experiments. It was found that various confinement protocols can drive the formation of an even denominator FQH effect in the second LL Fu et al. (2016). But the direct application of a weak in-plane electric field in the Corbino geometry Zhu et al. (2018) did not show

enhancement of the strength of the $5/2$ state as expected Tylan-Tyler and Lyanda-Geller (2017). Pressure and strain can play a role in orientation of the nearby nematic phase Koduvayur et al. (2011) discussed below. They were found to reduce the gap at $5/2$ and drive a transition to the nematic phase Samkharadze et al. (2016), Schreiber and Cs  thy (2020), Schreiber et al. (2018).

In-plane magnetic field and sample tilt impacts the bulk gap

An in-plane field increases Zeeman energy in comparison to the Coulomb energy thus allowing a tuning of the ratio of these two energies. Increasing Zeeman energy would, in principal, favor states with higher spin polarization. Sample tilt in a fixed magnetic field was used to explore this ratio in the context of the important question of the polarization of the $5/2$ state (see Section “Surface acoustic waves, geometric resonance transport, light scattering, and Knight shift: Spin polarization”).

Sample tilt simultaneously alters several energy scales at once. For example, an in-plane field imposed by sample tilt can also alter the interaction by impacting finite thickness effects thus lowering the energy of competing ground states at $5/2$ Peterson et al. (2008a, 2008b). As a result, experiments find differing behavior depending upon width, density, and tilt angle. For example, increasing tilt lowers the transport gap in some samples Dean et al. (2008a, 2008b), Eisenstein et al. (1988, 1990), Xia et al. (2010), Zhang et al. (2010), while others find weak dependence Cs  thy et al. (2005), Wang et al. (2020) or even an enhancement Liu et al. (2012).

Sample tilt was found to introduce a competing anisotropic phase Du et al. (1999), Lilly et al. (1999), Pan et al. (1999a). The anisotropic phase is believed to be a compressible nematic (stripe) phase Fradkin et al. (2010), Koulakov et al. (1996), Moessner and Chalker (1996), Rezayi et al. (1999), Rezayi (2017), Schreiber and Cs  thy (2020). The general trend found to date Cs  thy et al. (2005), Dean et al. (2008a, 2008b), Eisenstein et al. (1988, 1990), Liu et al. (2012), Wang et al. (2020), Xia et al. (2010), Zhang et al. (2010) shows that increased tilt angles induce a transition from an isotropic incompressible state, to an anisotropic compressible state. For even larger tilt angles the anisotropy is observed to diminish with no transport gap observed.

Concomitant anisotropy and incompressibility have been reported as well. In addition to evidence reported in standard transport tilt experiments Liu et al. (2013), Xia et al. (2011), there is also evidence from optical methods Levy et al. (2016) and non-linear transport in the Corbino geometry Bennaceur et al. (2018) that there is concomitant FQH effect and charge density wave order even in the absence of tilt. Observation of FQH effect requires a gap. But charge density waves (assuming they cause anisotropy) tend to lead to compressibility. Concomitant FQH effect and anisotropy (and/or density wave order) is therefore at odds with the idea that the $5/2$ FQH effect derives from a spatially uniform incompressible quantum Hall liquid. Observations of coexisting orders could also derive from domain formation Wan and Yang (2016).

Optical probes of the bulk gap

An incompressible FQH state requires a bulk collective-mode gap at all wavevectors. Optical studies of FQH states can be used to probe the bulk gap at many different wavevectors, not just the large wavevectors assigned to the transport gap. Since optical wavelengths are much smaller than the magnetic length, optical probes would be expected to create nearly zero-wavevector excitations. But the breakdown of translational invariance through, e.g., disorder, allows access to other wavevectors Das Sarma and Pinczuk (1996).

Several optics experiments at $5/2$ reveal a uniform incompressible state as expected from transport experiments Du et al. (2019), Levy et al. (2016), Rhone et al. (2011), Stern et al. (2010b), Wurstbauer et al. (2013) [Note, however, that there is evidence of domain formation Rhone et al., 2011.]. Wurstbauer et al. (2013) report evidence of gapped low-lying excitations at $5/2$ using resonant inelastic light scattering. The excitations observed here are reported to be consistent with spin-conserving roton-like neutral modes (see Section “Surface acoustic waves, geometric resonance transport, light scattering, and Knight shift: Spin polarization”). These results are also consistent with recent resonant inelastic light scattering experiments where the intra-LL plasmon spectrum characteristic of a nematic phase was observed to have a pronounced minimum at $5/2$ Du et al. (2019). Du et al. (2019) argued that this was evidence for the strength of the uniform liquid paired state. Optical probes have also been used to infer spin polarization as discussed in the following section.

Surface acoustic waves, geometric resonance transport, light scattering, and Knight shift: Spin polarization

Anti-symmetry of the total electron wave function requires that odd l -wave chiral BCS pairing of composite fermions be in a symmetric spin state, e.g., full spin polarization. The Pfaffian wave function and other non-Abelian wave functions considered in the literature (see Table 3) usually assume full spin polarization. Full spin polarization is therefore believed to be an important condition for non-Abelian quasiparticle candidate states that have received the most attention in the literature. Although one can, in principle, construct non-Abelian states without full spin polarization, see, e.g., Barkeshli and Wen (2010a, 2010b), Faugno et al. (2019), Yang and Rezayi (2008). The following section reviews experimental findings regarding the assumption of full spin polarization.

Surface acoustic waves and geometric resonance

Pairing of composite fermions in a fully polarized state requires a fully polarized composite fermion Fermi sea Read and Green (2000) that can be thought of as originating from a composite fermion Cooper instability Scarola et al. (2000a). Surface acoustic wave measurements were used to deduce the existence of a composite fermion Fermi sea in the half-filled lowest LL ($\nu = 1/2$) Willett et al. (1993) and a later measurement Willett et al. (2002) at $5/2$ revealed similar Fermi surface properties, although at $5/2$ the temperature had to be tuned to be high enough to leave behind a gapless composite fermion Fermi sea at $5/2$. Subsequent geometric

resonance measurements Hossain et al. (2018), Mueed et al. (2017) went further to reveal evidence for a fully polarized Fermi sea near $5/2$. These experiments thus provide evidence for an underlying polarized composite fermion Fermi sea that sets the stage for an instability to a fully polarized incompressible paired state at low temperatures at $5/2$.

Transport

We now turn to transport experiments designed to infer the polarization of the gapped $5/2$ state. Tilted field transport gap measurements were the first to be used to infer the ground state polarization Csáthy et al. (2005), Dean et al. (2008a, 2008b), Eisenstein et al. (1988, 1990), Liu et al. (2012), Wang et al. (2020), Xia et al. (2010), Zhang et al. (2010). But as discussed above, the presence of competing ground states with tilt complicates these interpretations. Early studies found a collapse of the transport gap upon tilt which was interpreted as evidence for an unpolarized (or partially polarized) state Eisenstein et al. (1988, 1990). However, the subsequent observation of a competing anisotropic phase at higher tilt Lilly et al. (1999), Pan et al. (1999a) shows that the reduction of the $5/2$ transport gap was most likely due to competing phases for these parameters Dean et al. (2008a), Friess et al. (2014).

Density tuning, as opposed to sample tilt, was used as an alternate route to explore ground state polarization as inferred from the transport gap. Density and magnetic field dependence over a wide range initially showed Pan et al. (2001) no transition (in support of a full polarization). But subsequent studies Pan et al. (2014), Samkharadze et al. (2017) found evidence consistent with a spin transition from a fully polarized state at high density to an unpolarized state at low densities where LL mixing may play a strong role.

Light scattering

Light scattering has been used to probe the polarization and excitations of the $5/2$ state. Polarization resolved photoluminescence spectroscopy at $5/2$ exhibited a sharp drop near $5/2$ which was initially interpreted as evidence for an unpolarized state Stern et al. (2010b). And a combination of elastic and inelastic resonant scattering reveals a spin-excitation continuum that suggests competing phases and possibly polarized/unpolarized domains slightly away from filling $5/2$ Rhone et al. (2011). But later resonant inelastic light scattering revealed spin waves only very close to filling $5/2$ Du et al. (2019), Levy et al. (2016), Wurstbauer et al. (2013) that were argued to reveal full (or nearly full) spin polarization.

Fig. 12 shows resonant inelastic light scattering data from Wurstbauer et al. (2013) performed at $5/2$. Sample tilt is used to impart finite momentum transfer in photon backscattering [For a review of these methods see, e.g., Das Sarma and Pinczuk, 1996.].

Fig. 12 (a) Resonant inelastic light scattering intensities measured at $\nu = 5/2$ as a function of the incoming photon energy. The inset shows spectra at energies marked by horizontal arrows in the color plot. E_z labels the Zeeman energy to show evidence for spin-wave modes. (b) Empirical wavevector ($q\ell_0$) dispersion based on the observed resonant inelastic light scattering mode energies showing at least one deep roton minimum at energy Δ_R . Δ_0 and Δ_∞ label the small and large wavevector gaps, respectively. The inset shows a schematic of the optical transitions between the valence band (VB), conduction band (CB), and the LLs labeled by N . ω_L and ω_S label the incoming and scattered photon frequencies, respectively. The figure is taken from Wurstbauer U, West KW, Pfeiffer LN, and Pinczuk A (2013) Resonant inelastic light scattering investigation of low-lying gapped excitations in the quantum fluid at $\nu = 5/2$. *Physical Review Letters* 110: 026801. <https://doi.org/10.1103/PhysRevLett.110.026801> with permission.

Fig. 12 reveals both a magnetoexciton collective mode (see Section “Overview of numerical results”) and small wavevector spin wave modes excited near the Zeeman energy. The coexistence of these modes was interpreted to be consistent with a fully polarized state with a magnetoexciton, as expected for polarized candidate states such as the Pfaffian and anti-Pfaffian. A gapless mode was also found at fillings slightly away from $5/2$, consistent with other optical experiments Rhone et al. (2011). These and other light scattering data therefore provide evidence for a gapped fully spin polarized state at fillings very close to $5/2$ but a gapless mode (possibly due to domain formation or competing phases) slight away from filling $5/2$ Du et al. (2019), Levy et al. (2016), Rhone et al. (2011), Stern et al. (2010b), Wurstbauer et al. (2013).

Knight shift

Strong evidence for full spin polarization at $5/2$ also came from resistively detected nuclear magnetic resonance experiments Stern et al. (2012), Tiemann et al. (2012). These experiments rely on the hyperfine interaction between the electrons in the GaAs quantum well and the atomic nuclei. Shifts in the nuclear resonance frequency are used to infer the polarization of the electron gas (Knight shift).

Fig. 13 shows data from Tiemann et al. (2012). The data show that the ferromagnets expected at fillings $\nu = 1$ and $\nu = 1/3$ are nearly fully polarized whereas the data at and near $\nu = 5/2$ reveal full polarization (within error bars). These and other Knight shift data were interpreted as evidence for full spin polarization Stern et al. (2012), Tiemann et al. (2012) although some theory work suggests interpretation of full polarization is not always justified Chesi and Loss (2008).

Tunneling with QPCs and SETs: Quasiparticle charge and edge exponents

Candidate ground states at $5/2$ all have dominant quasiparticle charges of $e/4$ (see Table 3). Experiments conclusively identifying bulk quasiparticle charge of $e/4$ are therefore crucial in confirming that the ground state at $5/2$ is a paired state, a necessary condition before detecting their non-Abelian nature. Edge theories of various proposed states also rely on assumptions regarding quasiparticle charge. Many different edge tunneling exponents are predicted from these theories (Table 3). The tunneling exponent, g , is inferred from tunneling conductance measurements (see Section “Properties of anyons”). The following reviews experimental determination of quasiparticle charge and tunneling exponents with QPCs and SETs at filling $5/2$.

QPC tunneling

Shot noise in tunneling across a QPC can be used to determine quasiparticle charge of a FQH liquid Girvin and Yang (2019). Initial work Dolev et al. (2008) found evidence for $e/4$, although subsequent work Dolev et al. (2010) finds the charge to be higher than expected when in a regime of very weak backscattering probability and sufficiently small excitation energies. Here the measured value of charge was found to vary with temperature and applied voltage. This puzzling result might be explained by the transport properties at low energies being dominated by agglomerate excitations with charge $e/2$, rather than the $e/4$ quasiparticles (Carrega et al., 2011). These two contributions may be distinguished by finite-frequency noise measurements (Carrega et al., 2012).

The quasiparticle charge can also be inferred from the detailed temperature and/or bias voltage dependence of QPC tunneling conductance. Here two parameters, the quasiparticle charge and the tunneling exponent are extracted. Several works Baer et al. (2014), Fu et al. (2016), Radu et al. (2008), Venkatachalam et al. (2011) extracted a quasiparticle charge consistent with

Fig. 13 (a) Longitudinal Hall resistance measured as a function of total filling factor in the presence of a radio frequency (rf) driving field. (b) The electron spin polarization (P) deduced from resistively detected nuclear magnetic resonance plotted as a function of total filling factor. The figure is taken from Tiemann L, Gamez G, Kumada N, and Muraki K (2012) Unraveling the spin polarization of the $\nu = 5/2$ fractional quantum Hall state. *Science* 335: 828–831. <https://doi.org/10.1126/science.1216697>.

or below $e/4$. The non-universality of the observed charge at $5/2$ is consistent with observations at other fractions [Feldman and Halperin \(2021\)](#).

SETs

SETs offered a method to extract local quasiparticle charge without relying on edge physics [Venkatachalam et al. \(2011\)](#). Here the inverse compressibility in a local region is measured and the quasiparticle charge is inferred from gate-tuned jumps. A value of $e/4$ was measured after disorder averaging. These experiments offer the most direct measurement of $e/4$ because they are local and avoid edge tunneling.

Edge exponents from tunneling conductance

Tunneling exponents extracted from tunneling conductance measurements can, unlike quasiparticle charge, be used to discern between various candidate states in [Table 3](#). The tunneling exponent (Section “Properties of anyons”) for the Majorana-gapped edge-reconstructed Pfaffian state is expected to be 0.5 [Overbosch and Wen \(2008\)](#). In weak backscattering tunneling conductance measurements [Baer et al. \(2014\)](#), [Fu et al. \(2016\)](#), [Lin et al. \(2012\)](#), [Radu et al. \(2008\)](#) the tunneling exponent was found to be smaller than 0.4 , which is consistent with Abelian states. But confinement was found to alter the value of the tunneling exponents [Fu et al. \(2016\)](#). This is consistent with more recent work which finds tunneling exponents that are incompatible even with established theories of the lowest LL, e.g., the $1/3$ state [Hennel et al. \(2018\)](#) [see also Section VIII in [Feldman and Halperin, 2021](#) for further discussion].

Noise in QPCs: Upstream neutral mode

Some candidates for the $5/2$ state possess topologically protected upstream neutral modes. These modes do not carry charge, so it is difficult to detect them in an electrical transport experiments. However, they carry energy and can generate excess upstream noise.

Noise in quantum point contact experiments have been used to detect the presence of upstream neutral modes at filling $5/2$ [Bid et al. \(2010\)](#), [Dolev et al. \(2011\)](#), [Gross et al. \(2012\)](#). The detection of upstream neutral modes would appear to cast serious doubt on the Pfaffian state in real samples since only downstream modes are expected (see [Fig. 4](#)). On the other hand, it has been pointed out that edge reconstruction would allow an upstream neutral mode in a Pfaffian state [Bid et al. \(2010\)](#), [Overbosch and Wen \(2008\)](#).

[Dolev et al. \(2011\)](#) went on to explore the nature of the upstream neutral modes. They compared those found at $5/2$ to those at $7/3$ and $8/3$ on the same device. They concluded that the neutral upstream modes are not due to edge reconstruction. Their conclusion casts doubt on the possibility of a Pfaffian ground state but supports an anti-Pfaffian state instead since it does possess an upstream neutral mode in the absence of edge reconstruction ([Fig. 4](#)).

Interferometry: Quasiparticle charge and braiding

Interferometry in the FQH regime relies on surface patterned gates to define multiple QPCs that guide edge currents in closed or open loops depending on gate voltages. The loops encircle Aharonov-Bohm fluxes to probe the accumulated phase of the wave function. The response of the device therefore depends on both the quasiparticle charge and the area enclosed. As a result, interference experiments can be used to measure both quasiparticle charge and quasiparticle braiding statistics. In this section we briefly review interferometry measurements of quasiparticle charge and braiding. More detailed discussion can be found in the reviews ([Carrega et al., 2021](#)) ([Feldman and Halperin, 2021](#)) and [Willett et al., 2013](#).

Interferometry and charge

The Aharonov-Bohm phase depends on the quasiparticle charge. Interferometry measurements near $5/2$ observed oscillations as a function of Aharonov-Bohm flux. The flux was tuned in two ways: magnetic field strength or area (tuned by a side gate). The observed oscillation patterns consistent with quasiparticle charge of both $e/4$ and $e/2$ were found [Willett et al. \(2009, 2010\)](#), but they coexist only at low temperatures. As temperature was increased, oscillations consistent with just $e/2$ charge survive. This was anticipated by [Wan et al. \(2008\)](#), who found the coherence length of the $e/4$ quasiparticles is much shorter than that of the $e/2$ quasiparticles, because the former involves the slow neutral mode velocity while the latter does not. As a result increasing temperature (which reduces coherence length) suppresses interference signal from the $e/4$ charge first.

Interferometry and braiding

We now review interferometry measurements that provide evidence for non-Abelian braiding statistics of quasiparticles in the $5/2$ state. Interferometry experiments are expected to reveal topological properties of anyons through anomalies in the Aharonov-Bohm effect [Bonderson et al. \(2006\)](#), [Das Sarma et al. \(2005\)](#), [de Chamon et al. \(1997\)](#), [Fradkin et al. \(1998\)](#), [Nayak et al. \(2008\)](#), [Stern and Halperin \(2006\)](#). A topological even-odd effect in interferometry was expected to lead to smoking-gun evidence of non-Abelian order (if present) derived from fusion rules summarized in [Fig. 2](#). Nevertheless, it was later argued that some Abelian orders can also demonstrate the same effect under certain circumstances [Stern et al. \(2010a\)](#).

Several works went on to report evidence for non-Abelian excitations in interference experiments [An et al. \(2011\)](#), [Willett et al. \(2013, 2019\)](#). In these experiments resistance oscillations as a function of magnetic field were observed (similar to the oscillations

used to infer quasiparticle charge). Here, however, periods consistent with the magnetic field needed to add one or more non-Abelian quasiparticles were observed as phase slips. The case for such oscillations were strengthened by controls done at filling 7/3 where only Abelian quasiparticles were expected. Willett et al. (2013) summarizes next steps and hurdles for operation of a device as described in Das Sarma et al. (2005). These include: phase stability, better control over device area, control of state changing current with time, and reproducibility in interference oscillations.

Summary of early experimental findings

We summarize early experimental support for assumptions underlying the possibility of candidate states hosting non-Abelian quasiparticles at filling 5/2. A culmination of experimental work finds that the bulk energy gaps measured in both optics and transport are consistent with theoretical models that account for finite thickness and LL mixing in a spin polarized state. It is expected that more realistic modeling that includes disorder would bring theory and experiment into better agreement. Furthermore, the culmination of evidence from both theory and experiment support the full polarization of the electrons in the half filled second LL, although there is some evidence of domain formation. All experiments tend to support a measured quasiparticle charge of $e/4$ with some evidence for an additional quasiparticle with charge $e/2$. Whereas results from quasiparticle edge tunneling, braiding, and shot noise have, so far, not been able to conclusively demonstrate sufficient conditions for non-Abelian quasiparticles.

Recent surprises and puzzles

The vast collection of experimental results reviewed in the previous section has provided invaluable insights into our understanding of the 5/2 state. Meanwhile, the underlying topological order remains elusive. This challenge can, in principle, be met by measuring the thermal Hall conductance,

$$K_H = c \left(\frac{\pi^2 k_B^2 T}{3h} \right) = ck_0 T. \quad (25)$$

Here, $c = c_d - c_u$ is the chiral central charge of the CFT describing the edge of the sample Cappelli et al. (2002), Kane and Fisher (1997), Read and Green (2000). Note that c_d and c_u are the total central charges for the downstream and upstream modes, respectively. When the edge of the quantum Hall system has counterpropagating edge modes, the interpretation of Eq. (25) becomes subtle. This issue will be discussed in Section “Partial equilibration on anti-Pfaffian edges”.

Two types of edge modes are relevant to the 5/2 state. A Bose mode has central charge 1 or -1 . This is independent of whether the mode is charged or neutral. A Majorana fermion mode has central charge $1/2$ or $-1/2$. The positive/negative value is adopted when the mode is downstream/upstream in both cases. Therefore, each topological order in Table 3 has its predicted thermal Hall conductance at $\nu = 5/2$ given by

$$K_H = 3 + \frac{c}{2}. \quad (26)$$

The first term on the right hand side originates from the three Bose modes that exist in any topological order describing the 5/2 state. All of them are running downstream. Note that $K_H < 0$ indicates that heat (or energy) flow along the edge in the opposite direction as the flow of charges, but the sign of K_H cannot be resolved in the usual two-terminal setup.

Experimental results

The first set of experimental data of thermal conductance measurement in the 5/2 state was reported recently in Banerjee et al. (2018). The data is shown in Fig. 14.

At temperature around 20 mK, K_H was nearly quantized at $2.5\kappa_0$. This result is very exciting as the half-integer quantized value for K_H strongly supports the non-Abelian nature of the 5/2 state. Meanwhile, the result remains puzzling. It does not agree with the theoretical predicted values, namely either $K_H = 1.5\kappa_0$ for anti-Pfaffian state or $K_H = 3.5\kappa_0$ for Pfaffian state. A more detailed analysis of the data also reveals a very rapid increase of K_H at low temperature (below 18 mK). This growth is much faster than any other filling factors Banerjee et al. (2017).

Possible interpretations

Both the unusual growth of K_H at low temperature and its nearly quantized value at $2.5\kappa_0$ can be explained naturally if the sample has the PH-Pfaffian edge structure (see Section “Theoretical background”). However, the PH-Pfaffian state has not received much numerical support as the Pfaffian or anti-Pfaffian state (see Section “Overview of numerical results”). The apparent tension between experimental data and existing numerical results motivated various proposals (or scenarios), which we now turn to.

Fig. 14 Thermal conductance as a function of temperature for the $5/2$ state in a GaAs heterostructure at electron number density $\rho \approx 3.0 \times 10^{10} \text{ cm}^{-2}$. Data is taken from Banerjee M, Heiblum M, Umansky V, Feldman DE, Oreg Y, and Stern A (2018) Observation of halfinteger thermal Hall conductance. *Nature (London)* 559: 205–210. <https://www.nature.com/articles/s41586-018-0184-1> with permission.

Bulk edge correspondence: PH-Pfaffian

As already mentioned, the most straightforward interpretation is that the bulk possesses the PH-Pfaffian order. Then, one would need to understand how to reconcile with existing numerical studies, which largely ignored effects of disorder and LL mixing, although the latter has been treated perturbatively in some cases. It was first suggested that the PH-Pfaffian state may be stabilized by a combination of LL mixing and disorder effects Zucker and Feldman (2016). Meanwhile, the stabilization of PH-Pfaffian state by sufficiently strong LL mixing alone in uniform systems was also proposed Antić et al. (2018), Milovanović et al. (2020). This idea is corroborated by demonstrating explicitly the possible emergence of the PH-Pfaffian state in translationally and rotationally invariant systems Sun et al. (2020). In particular, more than one LL needs to be involved in stabilizing the PH-Pfaffian state Milovanović and Djurdjević (2021).

Disorder induced Pf-APf domain walls

While it is challenging to include disorder directly in microscopic numerical studies, its effect can be studied in a more phenomenological manner. In the limit of zero LL mixing such that particle hole symmetry is preserved, the Pfaffian and anti-Pfaffian states are degenerate at $\nu = 5/2$. Disorder breaks the particle hole symmetry locally, and may induce Pfaffian and anti-Pfaffian domains. The domain walls are found to support gapless neutral (Majorana fermion) excitations, but have a charge gap Barkeshli et al. (2015), Wan and Yang (2016).

When the domain walls come close enough to each other, these neutral excitations can tunnel across the domain walls. The resulting percolation phase from the four copropagating Majorana fermions on each domain wall determines the thermal Hall conductance of the system. Using an effective network model, it was found that different phases can be realized in the system depending on the disorder strength (Lian and Wang, 2018; Mross et al., 2018; Wang et al., 2018). An effective field theory was further proposed in Hsin et al. (2020) to capture the qualitative features of the phase diagram found in Lian and Wang (2018). In principle, there is a phase with $K_H = 2.5\kappa_0$ and share the topological properties of the PH-Pfaffian state. Nevertheless, this phase is not favored for generic parameters in the network model analyzed by Wang et al. (2018). Its realization requires either the assumption that it is only a subdominant phase nucleated in the domain walls, or constraining the scattering events for Majorana fermion modes along domain walls by additional symmetry.

Using the technique of density matrix renormalization group, subsequent work studied the energetics of domain walls. It was originally concluded that the formation of domain wall is energetically unfavorable Simon et al. (2020). However, the later work Zhu et al. (2020) suggested that the intrinsic electric dipole moment emerging at the interface not taken into account in Simon et al. (2020) can stabilize the Pfaffian and anti-Pfaffian domains under experimental conditions.

The domain states discussed here are quite similar to the stripe state of Wan and Yang (2016) [proposed before the experiment Banerjee et al., 2018], where stripes (or domains) of Pfaffian and anti-Pfaffian states form spontaneously. Such a state restores particle-hole symmetry on average.

Partial equilibration on anti-Pfaffian edges

In the above two scenarios, one holds the view that the realistic sample has the PH-Pfaffian edge structure, although they have different bulk origins. This is reasonable because the value $2.5\kappa_0$ is only consistent with the PH-Pfaffian state (see Table 3). At the same time, this conclusion actually relies on the assumption that the edge of the sample is fully equilibrated. When the edge has downstream modes only, this assumption is always satisfied independent of the system size. Then, the thermal Hall conductance should agree with the theoretical predicted value in Eq. (25).

The situation becomes more subtle if the edge has counterpropagating modes. In this case the downstream and upstream modes along the same edge originate from two different sources at different temperatures [Banerjee et al. \(2018\)](#). The distance required for a pair of counterpropagating edge modes to reach thermal equilibration is known as the thermal equilibration length, denoted as ℓ_{eq} . In order to achieve a complete thermal equilibration on the edge, the length of the edge, denoted as L , needs to satisfy $L \gg \ell_{eq}$ [Aharon-Steinberg et al. \(2019\)](#), [Banerjee et al. \(2017\)](#).

The above subtlety gives rise to a possible reconciliation between the experimental data and the realization of anti-Pfaffian state in the sample (including the edge). When the edge is fully equilibrated, the anti-Pfaffian state has $K_H = 1.5\kappa_0$. This is because the net central charge of the edge theory is given by $c = 3 - 3(0.5) = 1.5$. On the other hand, the two central charges of a pair of counter-propagating edge modes should add instead of subtracting each other if these two modes do not equilibrate. Hence, K_H/κ_0 can be as large as $3 + 3(0.5) = 4.5$ in the anti-Pfaffian state, if all upstream modes do not thermally equilibrate with the downstream modes. For the measured value $K_H = 2.5\kappa_0$, it can be explained by partial thermal equilibration on the anti-Pfaffian edge. For the details of the mechanism, various proposals were introduced and debated [Asasi and Mulligan \(2020\)](#), [Feldman \(2018\)](#), [Ma and Feldman \(2019a\)](#), [Simon \(2018a, 2018b\)](#), [Simon and Rosenow \(2020\)](#).

Recent and ongoing developments

In an attempt to distinguish the above scenarios, several subsequent experimental and theoretical studies have been carried out.

Temperature dependence of ℓ_{eq}

Besides the value $2.5\kappa_0$, it is also important to explain the unusually rapid growth of K_H at low temperature. An increase of K_H at low temperature is actually reasonable because ℓ_{eq} is temperature dependent. Most of the topological orders (with both downstream and upstream edge modes) have $\ell_{eq} \sim T^{-2}$. For a sample edge with length L , the ratio L/ℓ_{eq} decreases as T is lowered. This can lead to a lack of thermal equilibration on the edge, and leads to an increase in K_H at low temperature [Aharon-Steinberg et al. \(2019\)](#), [Banerjee et al. \(2017\)](#).

The special structure of the PH-Pfaffian edge poses stringent constraints on possible interaction terms that couple the downstream Bose mode ϕ_c and the single upstream Majorana fermion mode ψ (see [Fig. 4](#)). The most relevant interaction is described by the operator,

$$\hat{O}(x) = \eta(x) \partial_x \phi_c (\psi \partial_x \psi), \quad (27)$$

with $\eta(x)$ being a random variable in space. The scaling dimension of $\hat{O}(x)$ is $\Delta = 3$, which is larger than the usual operators that couple two counter-propagating Bose modes, or a downstream Bose mode and a pair of different upstream Majorana fermion modes. In the language of renormalization group, $\hat{O}(x)$ describes a more irrelevant process and leads to $\ell_{eq} \sim T^{-4}$ in the PH-Pfaffian edge [Ma and Feldman \(2020\)](#). This exceptional dependence in temperature for the thermal equilibration length may explain the unusual rapid growth of K_H at low temperature, if the system has the PH-Pfaffian edge structure.

Interface experiments

One of the main differences among possible candidates for the $5/2$ state is the number and chirality of neutral modes on the edge. Thus, it is desirable to probe them more directly. By placing a region with $\nu = 5/2$ close to another region with $\nu = 2$ or $\nu = 3$, a resulting $5/2-2$ or $5/2-3$ interface is formed. Some of the original edge modes are gapped out or become localized along the interface. For Pfaffian, anti-Pfaffian, and PH-Pfaffian edges, the modes that remain freely propagating along the interfaces are illustrated in [Fig. 15](#). An important consequence is that these gapless modes dominate both charge and energy transport along the interface.

Fig. 15 Schematic diagram for the freely propagating (gapless) modes along the $5/2-2$ and $5/2-3$ interfaces when the $5/2$ state has Pfaffian, anti-Pfaffian, or PH-Pfaffian edge. The solid lines and dashed lines label Bose charge modes and neutral Majorana fermion modes, respectively. The square with label A and S represent respectively the amplifier and source. The effective interface length is defined as the distance between A and S. A hot spot (denoted as the fire mark) is formed at the back of the source when a dc current is injected at the interface from S. Depending on the gapless modes' chirality, excess noise may be measured at the amplifier or not. Note that the direction of magnetic field was reversed in the experiment when switching from the $5/2-2$ to the $5/2-3$ interface, so that the positions of the source and amplifier needed not be interchanged.

By injecting a dc source current at the interface, a hot spot will be created at the back of the source. Relatively short interfaces (28 μm , 38 μm , 48 μm , and 58 μm) were employed in the experiment that realized thermally unequilibrated transport. In this regime, shot noise will be detected at the amplifier when there are gapless modes propagating away from the source to the amplifier. In the experiment, shot noise was observed in both $5/2-2$ and $5/2-3$ interfaces Dutta et al. (2022b). If one neglects the possibility of reconstruction along the interface, the experimental result is only achievable if the original $5/2$ state has the PH-Pfaffian edge. This is because the PH-Pfaffian edge is the only one that remains unchanged under particle hole transformation. Furthermore, it has been theoretically proposed that electrical conductance measurement in a device that simultaneously contains both $5/2-2$ and $5/2-3$ interfaces could also identify the Pfaffian, anti-Pfaffian, and PH-Pfaffian edges uniquely Yutushui et al. (2022).

Another subsequent experiment was performed to measure the thermal conductance of the $5/2-2$ and $5/2-3$ interfaces Dutta et al. (2022a). In order to achieve thermal equilibration for a proper thermal conductance measurement, a much longer interface with length 160 μm was used. The measured values for the $5/2-2$ and $5/2-3$ interfaces were $(0.55 \pm 0.02)\kappa_0$ and $(0.53 \pm 0.02)\kappa_0$, respectively. For Pfaffian and anti-Pfaffian edges, either the resulting $5/2-2$ or $5/2-3$ interface will have a pair of copropagating Bose and Majorana fermion modes. These two modes are always equilibrated, so $K_H/\kappa_0 = 1.5$ is expected. Hence, the observed values in experiment favors the PH-Pfaffian edge in the original $5/2$ state.

Summary of recent developments

To summarize, the results from recent experiments have provided increasing support for the realization of PH-Pfaffian edge in the $5/2$ state. This edge structure is also consistent with previous results from tunneling experiments and the observation of upstream neutral modes. On one hand, the bulk-edge correspondence suggests that the bulk of the sample should be also described by the PH-Pfaffian state. On the other hand, the domain-wall picture hints at a possible difference between the bulk and the edge of the sample. Therefore, the underlying nature of the $5/2$ state is still an open problem.

Future directions

In this section, some possible future research directions for the $5/2$ state are listed.

Noise measurements

Besides the thermal conductance and interface experiments reviewed in the previous section, there are some recent theoretical proposals to identify the Pfaffian, anti-Pfaffian, and PH-Pfaffian edges via noise measurements. The corresponding results can further strengthen the support for or challenge the realization of PH-Pfaffian edges in real samples.

Shot noise in dc transport

It has been proposed that the combination of thermal conductance and shot noise measurements in dc transport can uniquely distinguish between the Pfaffian, anti-Pfaffian, and PH-Pfaffian edges. In addition to the edge modes coming from the second LL as shown in Fig. 4, all states at $\nu = 5/2$ have two additional edge modes originating from the lowest LL.

Depending on the sample edge length, it is possible that edge modes from the second LL equilibrate among themselves, but not with those from the lowest LL Ma and Feldman (2019a). In this scenario, both anti-Pfaffian and PH-Pfaffian edges will show $K_H = 2.5\kappa_0$. However, the predicted shot noises in dc measurement are distinct for these two edges. Only the anti-Pfaffian edge will generate a nonvanishing shot noise Park et al. (2020). For more details of the topological classification of noises in different types of edges, see Spånslätt et al. (2019). For the Pfaffian edge, it has no upstream modes. Thus, $K_H = 3.5\kappa_0$ independent of the sample edge length. At this moment, there is no proposal for the reconciliation between the thermal conductance data with the Pfaffian edge.

Thermal tunneling noise across a QPC

The scaling dimension of quasiparticles probed in tunneling experiments may help identify the edge structure of the $5/2$ state. However, existing results depend sensitively on the device configuration and lead to ambiguous interpretations. It has been suggested that such an ambiguity could be removed by measuring the thermal tunneling noise across the QPC Schiller et al. (2022). This noise is generated due to quasiparticle tunneling, and should be defined as the excess noise away from the usual Nyquist-Johnson noise. In particular, the associated Fano factor will show different dependencies on the temperatures of the two edges and the voltage bias across the QPC, when the scaling dimension of the tunneling quasiparticle is changed. This feature allows one to distinguish between the anti-Pfaffian and PH-Pfaffian edges.

Local power measurement in multi-terminal thermal conductance experiment

The thermal conductance data reviewed in Section “Recent surprises and puzzles” was taken from a two-terminal setup, which cannot resolve the sign of K_H . Neither can it give a universal value of $|K_H|$ when the edge is not fully equilibrated. This leads to ambiguous interpretation of the experimental result. It is important to develop techniques for measuring K_H reliably, that should work independent of the equilibration on the sample edge.

In a very recent work, a multi-terminal measurement on thermal conductance was performed [Melcer et al. \(2022\)](#). Using the new setup, the power carried by the downstream and upstream edge modes can be measured separately. From this, K_H can be deduced properly from $K_H = K_d - K_u$, where K_d and K_u denote the thermal conductance for the downstream and upstream modes, respectively. At $\nu = 2/3$, the new setup gives $K_H = (0.04 \pm 0.03)\kappa_0$, which agrees with the theoretical predicted value, $K_H = 0$ for an equilibrated edge at $\nu = 2/3$. It would be natural to generalize the same kind of measurement to the $5/2$ state. The result can provide another piece of information to help differentiate between the PH-Pfaffian and partially equilibrated anti-Pfaffian edges.

Other interferometry experiments

Direct measurement of braiding statistics of quasiparticles is an ideal probe of the topological order of a FQH liquid. While the Fabry-Pérot interferometer has become a commonly used device for detecting non-Abelian statistics, there are some caveats in this technique which were discussed in Section “Interferometry and braiding”. The topological even-odd effect was originally proposed as a smoking-gun signal of non-Abelian nature of the $5/2$ state [Bonderson et al. \(2006\)](#), [Stern and Halperin \(2006\)](#). However, it was later discovered that the Abelian 331 state [Stern et al. \(2010a\)](#), and all other Abelian states (except the $K = 8$ state) in the 16-fold way can mimic the same effect if the two types of $e/4$ anyons exhibit flavor symmetry [Ma and Feldman \(2019b\)](#). It will be important to include these caveats in future experimental designs to better delineate expected order at $5/2$.

A recent breakthrough on interferometry at $\nu = 1/3$ in the lowest LL has significant implications for detection of non-Abelian excitations at $\nu = 5/2$ [Nakamura et al. \(2019\)](#). In [Nakamura et al. \(2020\)](#), Fabry-Pérot interferometry was used to directly observe Abelian anyon statistics at $\nu = 1/3$. Normally, such experiments are done in a regime where the strong Coulomb interaction between edge states and the bulk of the interferometer complicates interpretation of signals of anyonic phases. But samples used in [Nakamura et al. \(2020\)](#) incorporate epitaxially grown layers used to screen (and therefore soften) these interactions. The net result was a robust Aharonov-Bohm interference in the fractional quantum regime showing clear phase slips consistent with Abelian anyon fractional statistics. Application of these seminal developments to $\nu = 5/2$ is a logical next step.

Mach-Zehnder interferometry

Issues in discerning topological orders can be circumvented by employing the Mach-Zehnder interferometer [Ji et al. \(2003\)](#), [Law et al. \(2006\)](#), [Ponomarenko and Averin \(2007, 2010\)](#). Previous work discovered that the corresponding signatures (i.e., tunneling current and Fano factor) for each individual state in the 16-fold way are different [Feldman and Kitaev \(2006\)](#), [Feldman et al. \(2007\)](#), [Ma and Feldman \(2019b\)](#), [Wang and Feldman \(2010\)](#), [Yang \(2015\)](#), [Zucker and Feldman \(2016\)](#). Although it is much harder to fabricate an Mach-Zehnder interferometer than a Fabry-Pérot interferometer, the former was employed to yield evidence of fractional statistics of anyons in the FQH state at $\nu = 2/5$ [Kundu et al. \(2022\)](#). It will be highly desirable to perform the same experiment for the $5/2$ state.

Non-Abelian anyon collider

Besides the result from the standard Fabry-Pérot interferometry [Nakamura et al. \(2020\)](#), fractional statistics of anyons in the Laughlin state at $\nu = 1/3$ was also observed in an anyon collider setup [Bartolomei et al. \(2020\)](#), [Rosenow et al. \(2016\)](#). In a recent preprint [Lee and Sim \(2022\)](#), it has been proposed that the latter technique may also differentiate among non-Abelian statistics of anyons in the Pfaffian, anti-Pfaffian, and PH-Pfaffian states. This may be achieved in future experiments.

Bulk probes: Polarized Raman scattering and thermal power

While the bulk edge correspondence is a very powerful tool in studying topological phases, there is the possibility of its breakdown in realistic samples due to various complications at the edge as discussed earlier. In fact the edge physics of the Laughlin $1/3$ state is still not yet completely understood [Chang \(2003\)](#), most likely due (at least in part) to edge reconstruction [Wan et al. \(2002, 2003\)](#), [Yang \(2003\)](#). It would thus be highly desirable to go beyond edge physics and probe the $5/2$ state (and other FQH states, Abelian or non-Abelian) in the bulk more directly in future experiments. We review some existing theoretical proposals below.

It was found that the graviton or magnetoroton in the Pfaffian state has a polarization -2 [Liou et al. \(2019\)](#), just like the Laughlin state. Since the chirality of the graviton is reversed under particle hole transformation [Liou et al. \(2019\)](#), [Son \(2019\)](#), the associated graviton in the anti-Pfaffian state has a polarization $+2$, as seen in numerics [Haldane et al. \(2021\)](#). The situation becomes more subtle in the PH-Pfaffian state. Due to particle hole symmetry, it is expected that gravitons (if they are present) should come with both polarizations (± 2) .

In order to excite the graviton mode, a net angular momentum $+2$ or -2 needs to be transferred to the sample. This may be implemented by using Raman scattering with circularly polarized light [Golkar et al. \(2016b\)](#). Importantly, the absorption of a photon can occur only if the incoming photon has the correct polarization. For example, the incoming photon must have the polarization -1 in order to excite the graviton mode in the Pfaffian state [Liou et al. \(2019\)](#). On the other hand, the graviton mode in the anti-Pfaffian state requires an incoming photon with polarization $+1$. The emitted photon must have the opposite polarization such that the net angular momentum transfer is ± 2 for anti-Pfaffian and Pfaffian respectively. For the PH-Pfaffian state, roughly equal absorption of both kinds of polarized photons is expected [Haldane et al. \(2021\)](#), [Nguyen and Son \(2021\)](#). Suppose the sample contains Pfaffian and anti-Pfaffian domains, the same technique can also reveal this structure if the spatial resolution of the experiment is finer than the typical sizes of the domains. Since Raman scattering has already been performed in studying GMP

modes in other quantum Hall states, it offers a huge potential in identifying the precise nature of the $5/2$ state in future experiment, which goes beyond the knowledge from edge probes.

The polarized Raman scattering discussed above directly probes the chirality of the FQH state (namely, whether it is electron-like or hole like), but not the nature of its quasiparticles. The latter, on the other hand, can be probed using bulk thermoelectric and thermodynamic measurements Barlas and Yang (2012), Cooper and Stern (2009), Gervais and Yang (2010), Yang and Halperin (2009). More specifically, such experiments can (potentially) measure the logarithm of the quantum dimension of the non-Abelian quasiparticles, which is the topological entropy they carry (Abelian quasiparticles have quantum dimension one and thus carry no topological entropy). Subsequent thermal power experiments have yielded encouraging but not yet definitive results Chickering et al. (2010, 2013). It would be highly desirable to continue this line of work.

Conclusion

The physics of the $5/2$ FQH state, most likely the first and only non-Abelian state of matter identified in nature at the time of writing, is extremely rich. This richness, revealed through enormous experimental, theoretical, and numerical effort, underlies the decades-long debate over the precise nature of the ground and excited states. Considerable progress has been made on all of these fronts, as we have reviewed here. The remaining unresolved puzzles that we have outlined in this chapter offer exciting opportunities for future research.

Acknowledgments

We would like to thank Ajit Balram, Matteo Carrega, Luca Chirolli, Gabor Cs  thy, Sankar Das Sarma, Dima Feldman, Moty Heiblum, Jainendra Jain, Thierry Jolicoeur, Sudhansu Mandal, Michael Manfra, Kwon Park, Edward Rezayi, Ganesh Sreejith, and Steve Simon for helpful suggestions and comments.
